VOL. XXXII. JANUARY, 1909. NO. 1.

THE JOURNAL

OF THE

American Chemical Society

REPORT OF THE INTERNATIONAL COMMITTEE ON ATOMIC WEIGHTS, 1910.

Received October 25, 1909.

Since the preparation of our last report there has been much activity in the determination of atomic weights. A brief summary of the results obtained is as follows:

Chlorine.—A novel comparison of chlorine with oxygen is due to Guye and Fluss.[1] Nitrosyl chloride, NOCl, was first weighed, and then distilled over silver, to absorb chlorine, then over heated copper, to absorb oxygen, and finally over metallic calcium, which retained the nitrogen. The complete analysis of the chloride was thus effected. From the direct weights of the oxygen and chlorine, Cl = 35.468.

Nitrogen.—In the investigation just cited, Guye and Fluss give data which correspond to N = 14.006. Guye and Pintza[2] determined the density of the mixed gases produced by the decomposition of ammonia, and so measured its composition by volume. If H = 1.0076, then N = 14.014. The authors regard the determination as having only a significance corroborative of the lower value for nitrogen.

The ratio AgCl : NH_4Cl : : 100 : 37.3217 has been measured by Richards, Koethner and Tiede.[3] Reduced with Ag = 107.881, Cl = 35.4574, and H = 1.0076, N = 14.0085. If H = 1.0078, N = 14.008. The values assigned to silver and chlorine are derived from former researches by Richards and his colleagues in the Harvard laboratory.

Carbon.—From the ratio between silver and tetraethylammonium bromide, as measured by Scott,[4] C = 12.017 when Ag = 107.88. A single experiment with the corresponding methyl compound gave C = 12.019. These values are too high to be accepted until they have been confirmed by other methods.

[2] *Compt. rend.*, **147**, 925.

[3] THIS JOURNAL, **31**, 6.

[4] *J. Chem. Soc.*, **95**, 1200.

From the density of methane, Baumé and Perrot[1] find C = 12.004. From the density of toluene, as determined by Ramsay and Steele, Leduc[2] computes C = 12.003.

Iodine and Silver.—Baxter and Tilley[3] have determined the ratio between iodine pentoxide and silver. The pentoxide was reduced by means of hydrazine, and the hydriodic acid so produced was balanced in the usual way against silver. From the ratio thus found, $I_2O_5 : 2Ag :: 100 : 64.6225$, and 64.6230 (two series), combined with the ratio I : Ag :: 100 : 84.8843, the authors find that the atomic weight of Ag lies between 107.847 and 107.850. The corresponding value for iodine is I = 126.891.

Phosphorus.—From the density of phosphine, PH_3, Ter Gazarian[4] finds P = 30.906.

Arsenic.—Atomic weight redetermined by Baxter and Coffin.[5] The ratios $Ag_3AsO_4 : 3AgCl$ and $Ag_3AsO_4 : 3AgBr$ were determined by two methods: one by solution and precipitation in the usual way, the other by heating the arsenate in a stream of hydrochloric or hydrobromic acid. The final, mean result is As = 74.957, when Ag = 107.880.

Chromium.—From analyses of silver chromate, by two methods, Baxter, Mueller and Hines[6] find Cr = 52.008 when Ag = 107.88. With similar analyses of silver dichromate, Baxter and Jesse[7] find Cr = 52.013. The mean value is 52.01.

Tellurium.—Lenher[8] converted the double bromide K_2TeBr_6 into 2KCl by heating, first in a stream of chlorine, and afterwards in hydrochloric acid. Sixteen very concordant experiments were made, giving the molecular ratio between the two compounds. The final mean value is Te = 127.55.

Mercury.—Analyses of mercuric chloride have been made by Easley,[9] who determined the proportion of mercury in the compound, and also the ratio $HgCl_2 : 2AgCl$. By the first method, Hg = 200.48; by the second method Hg = 200.62. These values are surprisingly high, but as Easley is to continue his investigation it would be unwise to accept them until his work is all done. It is quite possible that the increase may be ultimately verified.

Palladium.—Atomic weight determined by Gutbier, Haas and Gebhardt,[1] by analyses of palladosamine bromide. The final, most probable mean value, when $N_2H_6Br_2$ = 193.908, is Pd = 106.689.

[1] *J. prakt. Chem.* [2], 79, 457. This includes the work of Haas, cited in the report for 1909.

Krypton and Xenon.—Moore[1] isolated krypton and xenon in considerable quantities from the residues from 120 tons of liquid air. Calculated from the densities of the two gases the atomic weights are Kr = 83.012, and Xe = 130.70.

It will be seen from the evidence given above that few changes are needed in the table of atomic weights. Chromium, 52.01, may be rounded off to 52, as compared with the 52.1 formerly accepted. Arsenic becomes 74.96, in accordance with the work of Baxter and Coffin. The new values for krypton and xenon should also be adopted. As regards mercury, action may be deferred until more evidence is received.

FURTHER INVESTIGATION CONCERNING THE ATOMIC WEIGHTS OF SILVER, LITHIUM AND CHLORINE.

BY THEODORE W. RICHARDS AND HOBART HURD WILLARD.

Received October 28, 1909.

PART I.—THE RATIO OF LITHIUM CHLORIDE TO SILVER CHLORIDE AND SILVER.

Introduction.

The present uncertainty in the atomic weight of silver causes confusion and uncertainty throughout the whole table of atomic weights. Long ago Dumas[2] pointed out that Stas, with all his care, had not succeeded in preparing pure silver, and accordingly that the atomic weights referred to silver need revision. Later, in reply to Dumas, Stas[3] sought to determine the oxygen remaining in the metal and succeeded in finding only a trace. Hence for many years Dumas' criticism was unheeded. A careful study of Stas's experiments shows, however, that the metal which he used in these later trials had not been treated in the same way as that which he used in his work upon atomic weights and hence that the presence or absence of oxygen in the later samples proved little with regard to the earlier samples. As a matter of fact it was shown in 1903 in the chemical laboratory of Harvard University[4] that Stas's silver must have been impure to the extent of at least 0.015 per cent. and that therefore his value for the atomic weight of this element, as well as of the others which had been referred to it, must have been in error. Clearly Stas's value for silver must be too large, but no attempt was made at that time to discover just how great the error might be, this proof being a somewhat complicated matter. Since that time increasing evidence has been presented, especially by Guye, tending to show that the discrepancy is serious. Because most other elements are referred to oxygen only through silver, on account of the insolubility of many silver salts and their consequent ease of precipitation, this uncertainty in the atomic weight of silver is one of very serious moment. Indeed a majority of the atomic weights cannot be referred to oxygen with precision until the relation between silver and oxygen is ascertained without doubt.[1]

Chem.*, 47, 56 (1905). This paper is reprinted in full in "Experimentelle Untersuchungen über die Atomgewichte," by T. W. Richards, page 689 (Hamburg, 1909), and also in *Chem. News*, 93.

To discover the most suitable method of attaining this end, and to obtain the greatest accuracy possible in the solution of the problem, was the object of the present research. We were fortunate in being able to profit by previous experience, many of the difficulties having already been surmounted in previous investigations carried out in this laboratory.

Before discussing the present investigation, it will be helpful to review briefly the work previously done relating to the oxygen-silver ratio. Unfortunately no compound of silver and oxygen exists of a nature suitable for exact work. The two common oxides of silver are far too unstable to yield results possessing any precision, and moreover, the amount of oxygen in even the higher of these oxides is a comparatively small percentage of the whole. Hence the necessary errors of the determination are greatly magnified in the calculation. For this reason it is necessary, as Stas realized, to study a compound of silver and oxygen which contains some third element, and various salts are available for the purpose. Stas himself used chiefly the chlorates, bromates, and iodates for this purpose, determining the ratio $3O : Ag$ by multiplying together the values found by him for the following pairs of ratios, thus:

$$\frac{3O}{KCl}\cdot\frac{KCl}{Ag}=\frac{3O}{Ag};\quad \frac{3O}{AgCl}\cdot\frac{AgCl}{Ag}=\frac{3O}{Ag};\quad \frac{3O}{AgBr}\cdot\frac{AgBr}{Ag}=\frac{3O}{Ag};\quad \frac{3O}{AgI}\cdot\frac{AgI}{Ag}=\frac{3O}{Ag}.$$

In each case the first ratio was obtained by the decomposition of a halate (*i. e.*, a chlorate, bromate, or iodate) and the second ratio by the comparison of silver with a halide. If the exact identity of the halide obtained from each oxygen salt with that employed in the corresponding second process could be proved, and if the various substances had been pure, the method would have been an admirable one; but unfortunately neither of these important qualifications was completely attained. Moreover, other minor errors crept into the work.[1]

The nitrate and sulphate of silver were also studied by Stas, and his figures concerning these substances may be used in a similar way. These researches have been recently repeated with greater precision in this laboratory,[2] but here the outcome is complicated by the fact that the relation neither of nitrogen to silver nor of sulphur to silver is precisely known. Nitrogen, it is true, has been referred with much plausibility to oxygen, with the help of gas densities; but this is a physical rather than a chemical method of determining atomic weights. Excellent though it undoubtedly is as corroborative evidence, it cannot carry with it the conclusiveness which a chemical determination could furnish. On the other hand, the atomic weight of sulphur is far from certain.

Without attempting to give a complete historical discussion, the most important results of other investigations may be mentioned. The interesting and valuable results of Dixon and Edgar,[3] of W. A. Noyes[4] and H. C. P. Weber and of Edgar alone[5] upon the quantitative synthesis of hydrochloric acid furnish less direct evidence upon the matter in hand, for they need the introduction of two other ratios, namely, that of hydrogen to oxygen and that of chlorine to silver, in order to solve the problem. Thus:

$$\frac{2\mathrm{H}}{2\mathrm{Cl}} \cdot \frac{2\mathrm{C}}{2\mathrm{Ag}} \cdot \frac{\mathrm{O}}{2\mathrm{H}} = \frac{\mathrm{O}}{2\mathrm{Ag}}.$$

Even if the result were not burdened with all the errors which may reside in the additional figures, it would not be very satisfactory, because oxygen is compared with over thirteen times its weight of silver, and any error becomes greatly magnified in the calculation.

Simpler arithmetical manipulation is demanded by the recent interesting complete analysis by Guye and Fluss[6] of nitrosyl chloride, NOCl, but the result is still somewhat open to the last objection. Thus:

$$\frac{\mathrm{O}}{\mathrm{Cl}} \cdot \frac{\mathrm{Cl}}{\mathrm{Ag}} = \frac{\mathrm{O}}{\mathrm{Ag}}.$$

Here the weight of oxygen for a given weight of silver is double that in the last case.

A more promising method has been developed by Baxter,[7] and carried out with the assistance of G. S. Tilley, namely, the direct analysis by decomposition of iodine pentoxide. In this way may be determined with considerable accuracy the ratio $I_2 : 5O$ and by multiplying the results by the ratio of silver to iodine,[1] the ratio of $2Ag : 5O$ is at once obtained. Thus:

---

[1] The best discussion of this subject is to be found in Brauner's admirable discussion on "The Fundamental Atomic Weights" in Abegg's "Handbuch der anorganischen Chemie," II, 1, 177–182.

[7] Baxter and Tilley, THIS JOURNAL, 31, 201 (1909).

$$\frac{5O}{2I} \cdot \frac{2I}{2Ag} = \frac{5O}{2Ag}.$$

If the second ratio were known with the greatest accuracy, this method would be an excellent one, but the peculiar nature of silver iodide has interfered with the attainment of quite as certain results concerning this substance as concerning the other silver halides.

The values obtained for silver from these various methods range from 107.92, based upon Edgar's value for chlorine and Morley's value for hydrogen, to 107.85, based upon Baxter and Tilley's work with iodine pentoxide, and it is safe to conclude that the truth lies between these extremes. Nevertheless, the range of uncertainty (0.07, or distinctly over one-twentieth of one per cent.) is far too great for a datum of such importance.

The necessity for further work upon the ratio of silver to oxygen is very evident, and the present paper recounts an extended investigation, protracted over two years, which has furnished entirely new results of a nature apparently more trustworthy than any that had gone before.

As a first step, all substances which might possibly be available for obtaining further knowledge of this very important ratio were scrutinized with the greatest care, in order to determine whether or not a better starting-point might be found. Evidently, from the foregoing remarks, the selection of the substance for this purpose depends upon more than one consideration. In the first place, it is important that the actual weights of the two elements to be compared should not be very different, so that the error in one may not be greatly magnified in a calculation of the other; hence, because the atomic weight of oxygen is much smaller than that of silver, the comparison must involve several atoms of oxygen with one of silver, if possible. For this reason the most highly oxygenated salts were studied first. It is, moreover, necessary to choose a salt of such a nature that the two ratios $\frac{MXO_y}{MX}$ and $\frac{MX}{Ag}$ may each be accurately determined. With respect to each requirement, the perchlorates seemed to furnish a peculiarly suitable starting-point. It is indeed remarkable that all previous investigators have chosen to work with chlorates in preference to the perchlorates, which are more stable, contain more oxygen, and are more easily obtained pure.

---

[1] Baxter, *Proc. Am. Acad.*, 41, 73 (1905).

The choice among the perchlorates was determined by the other considerations which must always form an important factor in a choice of this kind, namely, the nature of the substances to be weighed. In order that accurate results may be obtained, it is obvious that all the substances whose precise weights come into consideration should be capable of complete purification and thorough drying, and the great difficulties attending these processes are governed largely by the specific nature of the substances. In order that a substance may be prepared in a pure state, it must be capable of easy crystallization in such a way as to free it from its usually attendant impurities; and in order that it may be dried, it must be capable of fusion without decomposition. There are no perbromates and the periodates are too unstable; among the perchlorates the only substance which corresponds to these specifications seems to be lithium perchlorate, which fuses at 236° and loses no oxygen at 300°. Fortunately in other respects this substance is peculiarly well suited for the purpose. Its decomposition products, if any, can be accurately determined. It crystallizes well, and its solubility has a large temperature coefficient; therefore it may be easily prepared pure. It is not deliquescent or markedly hygroscopic in fairly dry air. It can be synthesized from the chloride merely by the evaporation of this salt with a slight excess of perchloric acid, the less volatile perchloric acid easily expelling the more volatile hydrochloric acid. Finally it contains over 60 per cent. of oxygen—probably more available oxygen than any other known compound, not excepting anhydrous hydrogen peroxide. Ten cubic centimeters of the salt, weighing about 24 grams, contain enough oxygen to occupy, under normal conditions, nearly 10 liters, and all this oxygen is lost when the salt is converted into chloride. Lithium has the least atomic weight of any metal, and chlorine the least of any halogen which forms oxygen salts; therefore it is easy to see how this favorable circumstance comes to pass. Such a substance affords a far more satisfactory means of weighing a gas than any attempt to weigh it in an uncombined condition. When one considers the bulky apparatus necessary in weighing gases, with the attendant errors, and the unavoidable small weights of gas, it is easy to see the superiority of a process involving a solid salt, containing the gas in an exceedingly condensed form. The weighing of hydrogen absorbed by palladium, a method employed in the recent work on the synthesis of water, is an illustration of this point. In the present case, we may consider the lithium chloride as absorbing oxygen, but far more efficiently.

Lithium perchlorate was finally chosen, however, only after a careful study of the other perchlorates, in order to make certain that none of the others offered other advantages outweighing those peculiar to itself. Attention was first directed toward silver perchlorate, which is easily prepared by evaporating a solution of the nitrate with excess of perchloric acid, and expelling the free acid by heat. The salt is extremely deliquescent, and is difficult to dry without slight decomposition. Its fusing point is so high (486°) that it cannot be completely fused before violent decomposition begins, and for the same reason an accurate determination of the water remaining in the salt dried at a lower temperature, would be difficult, if not impossible. Silver perchlorate was, therefore, abandoned, although it has one great advantage—it is easily converted into chloride in a current of dry hydrochloric acid gas even at ordinary temperatures, the process involving no transfer of material. The reaction is not a reduction, anhydrous perchloric acid being formed.

The alkaline perchlorates were next investigated. Potassium perchlorate cannot be fused without rapid decomposition. Sodium perchlorate has a lower fusing point (482°), but it decomposes slowly at this temperature, and hence cannot be accurately weighed. All indications therefore pointed to lithium perchlorate, whose virtues have been already described.

The ratio of silver to oxygen cannot be determined from this salt, however, until that of lithium chloride to silver is known. Thus, writing the relation in a manner analogous to that employed in the case of the chlorates:

$$\frac{4O}{LiCl} \cdot \frac{LiCl}{Ag} = \frac{4O}{Ag}.$$

Our knowledge of this second ratio (LiCl : Ag) depended upon the doubtful work of Stas, and this was at best freighted with the known errors entering into this work upon potassium and sodium chlorides. Hence, an essential step in the new work was the determination of this ratio, and incidentally of the true atomic weight of lithium. Even if Stas's value for lithium had been precise, however, instead of as we found it, nearly a whole per cent. in error, there would still have been good reason for making this determination anew with the same material used in our work with the perchlorate ratio. If the same sample of lithium chloride is used in determining both ratios, it is evident that the value obtained for the oxygen-silver ratio is independent of any other atomic weight, and that the weight of the alkaline chloride is eliminated. It matters not whether this chloride is free from other alkaline metals or contains them. To use an impure lithium salt would be, of course, a waste of time; from such a substance the atomic weight of lithium could not simultaneously be found.

The methods of determining these two ratios $\frac{LiCl}{Ag}$ and $\frac{4O}{LiCl}$, are so widely different that they will be treated separately. While the ratio of silver to a chloride has so frequently been carried out in this laboratory that the operation presents no difficulties, the method for determining the amount of oxygen in the perchlorate was solved only after a long and careful research. The former of the two processes naturally precedes the latter; accordingly the determination of the equivalent of lithium chloride, referred both to silver and to silver chloride will be found in the first section of this paper. On the other hand the second section of the paper deals with the preparation of the perchlorate and the determination of the oxygen which it contains.

We take pleasure in expressing our obligation to the Carnegie Institution of Washington for generous pecuniary assistance throughout the course of the work.

History of the Revisions of the Atomic Weight of Lithium.

A glance at the following table, which shows the results so far obtained, reveals wide discrepancies.[1]

				Atomic weight.

Edinburgh*, **35,** II, 429.

All excepting one of these determinations was made more than forty years ago, and the most recent, made twenty years ago, involved the use of a questionable method. Hence it is clear that a redetermination of the atomic weight would be desirable, even if it were not essential for the precise evaluation of silver and oxygen with the help of lithium perchlorate. Lithium alone among the five alkali metals has not received reasonable attention in this respect in recent years.

Of these twenty-three values found for the atomic weight of lithium, only those given in the last column of the table referred to the standard Ag = 107.88 are worthy of serious consideration. A few words discussing their merits and defects, in chronological sequence, will not be misplaced.

Mallet in 1856 purified his lithium chloride by dissolving it in alcohol and ether, but Stas has shown[1] that by this method the salt cannot be separated from the chlorides of the other alkaline metals. He fused and weighed it in a covered platinum crucible—a process which must have given an alkaline product, in spite of the fact that ammonium chloride was added. Moreover, the hygroscopic nature of the chloride prevents it from being exactly weighed without greater protection from laboratory moisture. In two experiments the silver chloride was weighed, and in one the solution was titrated against a known weight of silver, following the method of Pelouze. The latter method in its old form gives too low results. The various errors seem to have counterbalanced one another, for the average value, 6.94, is almost exactly correct. This happy result could hardly have been foreseen, however.

Diehl purified his lithium by repeated precipitation with ammonium carbonate, thirty precipitations being required to free it from sodium. The lithium carbonate was then dissolved in sulphuric acid and treated with barium hydroxide, the lithium hydroxide thus obtained being converted into carbonate. This was dried at 130° and decomposed in a Bunsen apparatus by means of dilute sulphuric acid, the carbon dioxide being determined by the loss in weight of the apparatus. Four experiments were performed, the average value obtained being 7.03, but no vacuum corrections were applied, nor was a counterpoise used in weighing. The possibilities of uncertainty are so great that no one to-day would be disposed to accept the result without question.

Troost purified lithium carbonate by repeatedly dissolving it in cold water saturated with carbon dioxide and reprecipitating it by boiling the solution. In two experiments it was dried at 100°, mixed with powdered, ignited quartz, and the carbon dioxide determined by the loss of weight on heating. In one experiment it was converted into the sulphate. In two experiments lithium chloride was dehydrated in dry hydrochloric acid gas, which was afterwards displaced by dry air. The chlorine was determined by weighing as silver chloride, and the mean value obtained for the atomic weight was 6.96. This outcome possesses the virtues and defects of Mallet's work.

---

[1] Stas, *Oeuvres Completes*, 1, 691.

Dittmar purified lithium carbonate by the method of Troost, but did not obtain a pure salt. He fused it in a current of dry carbon dioxide, the pressure varying from one to two atmospheres. By this means the formation of oxide was prevented. The carbonate was decomposed by dilute sulphuric acid, the gas evolved being absorbed by potassium hydroxide and weighed. The work was ingenious but very crude; the mean of ten results varying more than one-half per cent. was 6.89.

Stas's work was far more careful than any cited above, although the final result was really not as accurate. He purified his lithium salt according to the methods of Diehl and of Troost. After removing most of the other metals by dissolving the chloride in alcohol and ether, the lithium was precipitated with ammonium carbonate seven times before it was found to be free from sodium. The lithium in the mother liquors was precipitated as carbonate, and this was purified by conversion into soluble bicarbonate, and reprecipitation of the solution by boiling—a very troublesome operation requiring several days. Two such treatments gave a product free from sodium. Both methods are extremely wasteful, 1200 grams of fairly pure carbonate yielding only 145 grams of the purest salt. This was converted into chloride by heating in a platinum boat to 175° in a current of dry hydrochloric acid gas. The chloride was then maintained in a state of fusion for twenty minutes, and finally cooled in nitrogen, after which it was weighed in a vacuum. The solid salt was subsequently dropped into a solution containing the theoretical amount of silver dissolved in nitric acid, and the titration was carried on exactly as in the work on sodium chloride. The errors incident to this process have been pointed out by Richards and Wells.[1] Impurity in the silver and occlusion of silver nitrate by silver chloride tended to lower the atomic weight; impurity in the lithium chloride, and the error of method of determining the end point, tended to raise it. Stas himself calculated as the mean atomic weight of lithium from three experiments 7.022, but this becomes 7.003 if modern values for silver and chlorine are substituted.

He also determined the ratio $LiNO_3 : LiCl$ by dissolving the chloride in water in a large flask, evaporating with excess of nitric acid, and finally fusing the nitrate. Using modern values for nitrogen and chlorine, the atomic weight of lithium calculated from the mean of three experiments, is 6.961—a value much more nearly correct than the other.

Stas always found his lithium chloride alkaline to litmus, even when it had been heated in hydrochloric acid until half the salt had volatilized.

---

[1] This Journal, 27, 459 (1905).

It is difficult to account for this fact, yet it helps to explain the excessively high value for the atomic weight which he obtained. His lithium chloride volatilized in hydrochloric acid without leaving any residue, but this would not preclude the possibility that chlorides of the other alkali-metals were present. In some later work on lithium,[1] he failed to obtain, by the means previously employed, a sample of lithium carbonate which would not show the sodium line upon very careful spectroscopic examination. It was necessary to volatilize in the oxyhydrogen flame, one-third or one-half of the carbonate, in order to obtain a residue of oxide absolutely free from sodium. From this oxide, he was unable to prepare pure lithium chloride, and he remarked that he believed it impossible to obtain that salt absolutely free from sodium unless every trace of dust could be excluded. It is obvious that the purification of lithium salts demands further attention.

Up to the present time, the most accurate work on this element has been usually supposed to be that of Stas. Since the errors in his work on the chlorides of potassium, sodium, and lithium are similar, and his values for the first two metals are too high, we should naturally expect the same to be true of lithium. The error was quite noticeable in the case of potassium, still more pronounced with sodium, and, as will be shown, was greatest of all with lithium.

In reviewing the foregoing results, which vary so widely, it seemed clear that the reason for the incompatibility of the values obtained for lithium, was to be sought not only in the methods of analysis, but also in the impurity of materials. Accordingly the first step of the present research was a careful study of the various practicable methods of purifying salts of lithium. The next procedure was obviously the application to the purest lithium material of the methods already so thoroughly studied in this laboratory in the cases of sodium and potassium. Some of the details of these methods were improved, and these improvements will be described in due course.

Balance and Weighing.

The excellent and sensitive Troemner balance which has served in many similar researches was used in the present work. Successive weighings of the same object rarely differed more than 0.02 mg.

The Sartorius gold-plated brass weights and rider were standardized from time to time by the method usually used at Harvard.[2] All weighings were made by substitution, using a counterpoise similar to the object which was being weighed, so that the weights required were never large in amount, and the influence of changes in atmospheric conditions was negligible.

[1] *Oeuvres Complètes*, III, 324.

[2] Richards, THIS JOURNAL, 22, 144 (1900).

The vacuum corrections applied were as follows, the density of the weights being 8.3.

	Density.	Vac. cor. per gram.
Silver	10.49	—0.000030
Silver chloride	5.56	+0.0000732
Lithium chloride[1]	2.068	+0.000436
Lithium perchlorate	2.428	+0.000350

The Preparation of Materials.

All the solid, liquid and gaseous materials used in this research were purified with the greatest care. The most insidious sources of impurity in work of this kind are dust and the various gases sometimes contained in the air of the laboratory, and the most efficient methods of purification may fail to give a pure product unless careful attention is paid to this fact. The presence of dust, which always contains sodium, was especially noticeable in the preparation of pure lithium salts, where sodium was the element most difficult to remove. It was found that a lithium salt free from sodium, after being recrystallized in the usual way, always acquired traces of this element. The air of the room was, therefore, kept as pure as possible, and all evaporation, and handling of solutions and salts in the final work, were conducted in a large glass case. Vessels containing pure material were always kept covered and under bell jars when not in use. When it was necessary to work under the hood, a large, clean glass plate was suspended above the apparatus, to protect it from particles of dust falling from above. All heating was conducted electrically in order to avoid the deleterious effects of products of combustion.

Since most of the heating apparatus was constructed in this laboratory during the progress of the work, a brief description of it may not be inappropriate. The resistance material was "nichrome," an alloy of nickel, iron and chromium, which withstands fairly well a temperature of 1000°. It was generally used in the form of a ribbon, 1.5 to 3 millimeters wide. A small electrical stove or hot plate for conducting evaporations was made by winding this ribbon on a quartz plate, which was then covered with another thin plate of the same material, and the whole suitably mounted and insulated with asbestos. Another form, particularly adapted for heating flasks and dishes, was made by winding layers of wet sheet asbestos and the ribbon concentrically till the desired size was obtained; the roll, while still moist, was then pressed against the vessel to be heated and shaped to fit it. When dry, the mass of asbestos with its embedded ribbon, retained its form, and was mounted on asbestos board. A drying oven was made by winding a three-liter beaker with the ribbon, and jacketing it with heavy asbestos. By cutting through this jacket at one place, a window was formed, through which the interior could be observed.

---

[1] Baxter, *Am. Chem. J.*, 31, 558 (1904).

A temperature of 400° was easily obtained. A porcelain tube for fusing silver was wound with the ribbon and then covered with thick asbestos. When it was desired to heat a glass tube, and at the same time observe the interior, the ribbon was left bare, and the convolutions were far enough apart so as not appreciably to obstruct the view. The value of electrical heating, both as to cleanliness and wide range of application, was emphasized in the present research.

The vessels used in purifying materials were usually of quartz or platinum. Where glass was unavoidable, the best Jena glass was employed.

Water.—Distilled water of the laboratory was twice redistilled, once from alkaline permanganate and once alone, using pure tin condensers, without rubber or cork connections.[1] In special cases the water was condensed and collected wholly in platinum. Dust was carefully excluded by passing the end of the condenser through a hole blown in the bulb of a small flask, which rested on the mouth of the large Jena flask in which the water was collected and stored. Water was always distilled just before use.

Nitric Acid.—Carefully tested pure nitric acid of commerce was redistilled, using a platinum condenser. When required to be free from chlorine the first portion was rejected and the acid redistilled until it showed no trace of this element when examined in the nephelometer.

Hydrochloric Acid.—The pure acid of commerce was boiled with a little pure potassium permanganate, and then repeatedly distilled, using a quartz condenser.

Ammonium Fluoride.—Baker's best hydrofluoric acid, which was already very pure, was distilled once in a platinum retort, and neutralized by distilling into it, through a platinum tube, pure ammonia from a concentrated solution of the gas.

Ammonium Carbonate.—The purest commercial salt was dissolved in water containing ammonia, and distilled in a platinum retort. Any trace of impurities contained in the product must have been volatile ones, which could exercise no harmful effect in the present case.

Hydrazine Hydrate.—This substance was prepared by distilling to dryness in platinum a mixture of hydrazine sulphate and potassium hydroxide in solution, using double the theoretical quantity of the latter substance. The resulting solution was distilled again from the small residue of alkali which had been carried over into it; the dilute portion coming over first was distilled yet once more in order to concentrate it, the first fractions, containing almost nothing but water being rejected. The substance was collected and preserved wholly in platinum, as were also the ammonia and ammonium fluoride.

Perchloric Acid.—This was prepared by a modification of the method of Kreider.[1] Since sodium perchlorate can now be obtained in large quantities, the preparation of the stable hydrated acid is a comparatively simple operation, quite free from the dangers and difficulties involved in preparing the unstable anhydrous compound.

---

[1] Richards, *Proc. Amer. Acad*, 30, 380 (1894); *Chem.-Ztg.*. 1907, No. 73, p. 899.

A saturated solution of sodium perchlorate was poured into two and one-half times its volume of pure concentrated hydrochloric acid (density, 1.20). After thorough agitation the sodium chloride was allowed to settle, the clear liquid was siphoned off, and the sodium chloride drained in a funnel by suction, and washed with a little more acid. The solution, containing hydrochloric and perchloric acids, with a little salt of sodium, was evaporated until dense white fumes of perchloric acid began to appear. The liquid was then found to be entirely free from hydrochloric acid. At this point the concentration of the perchloric acid is approximately that of the dihydrate—about 70 per cent. If distilled under ordinary pressure, where it boils at 203°, there is considerable decomposition, involving a loss of perhaps 10 per cent. The crude acid was therefore usually distilled under 150 to 200 mm. pressure, with almost no decomposition, but for the final distillation a pressure of 15 to 20 mm. was not exceeded. At first the acid was condensed in a platinum condenser bent at right angles and having its upper end slightly conical to fit into the constricted neck of a two-liter flask of resistant glass. The constriction was carefully ground until the platinum fitted it tightly. It was found that this joint held a vacuum very effectively after the flask and condenser had been pressed firmly together. The other end of the condenser passed through a rubber stopper fitted into a hole in a bell jar containing the platinum dish to receive the distillate. While the excess of water was being distilled off, the acid bumped rather badly; but when the concentration of the acid became that of the constant boiling mixture, this distilled rapidly and smoothly without any sign of ebullition. The yield is practically the theoretical.

Even when distilled under a pressure of 15 mm. the acid had a faint odor, resembling that of the oxides of chlorine. It seemed possible, therefore, that the hot liquid might attack slightly the platinum condenser, although no evidence of such an effect was observed. Accordingly, in preparing the purest acid, we decided to condense and collect it in quartz vessels. To the quartz condenser was attached the half-liter distilling flask, into the neck of which was fused a dropping funnel, terminating in a capillary at the bottom of the flask. In this way acid could be introduced continuously during the distillation. The connection between the flask and the quartz condenser gave much trouble. At first a carefully ground joint was used, the quartz forming the inner portion, but it was found that since the coefficient of expansion of glass is far greater than that of quartz, such a joint will invariably crack, even when exposed to a change of temperature of only 75°. If the outer portion is glass, it cracks on cooling; if quartz, on heating. The only possible joint between these two materials which will allow expansion and contraction, is one having two flat faces ground together as in Fig. 1.

---

[1] *Z. anorg. Chem.*, **9**, 343 (1895); *Am. J. Sci.* [3], **49**, 443. Kreider and Breckenbridge, *Z. anorg. Chem.*, **13**, 161 (1896); *Am. J. Sci.* [4], **2**, 263.

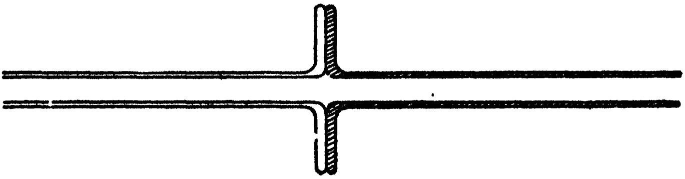

Fig. 1.

Such a joint is easily made by forming a collar on the end of each tube, grinding them until perfectly plane, and finally polishing with oil and rouge. The two faces are held tightly together by a rubber band or a spring. Such a joint, without any lubricant, held a vacuum very effectively, and was entirely unaffected by changes of temperature. The joint was so placed that any condensed liquid coming into contact with the glass part would run back into the distilling flask.

After at least three previous distillations, the acid was finally distilled through the quartz condenser directly into a quartz flask, and all possibility of introducing impurity in this process was avoided.

The question of the purity of the acid thus obtained was carefully investigated. All the possible impurities must be those present in the sodium perchlorate and hydrochloric acid, and the only acids likely to remain after concentrating the crude acid, are sulphuric and phosphoric; the others are either destroyed or volatilized.

In order to determine how readily sulphuric acid could be separated from perchloric, a mixture of the latter with two per cent. of sulphuric acid was fractionated. After three distillations in which only 10 per cent. was rejected, 90 per cent. of the last distillate proved to be entirely free from sulphuric acid and 9 per cent. more contained so little that the residue left after evaporating off all but 1 cc., showed a barely visible opalescence upon the addition of barium chloride. Phosphoric acid is even easier to remove. The residue remaining after the distillation of the crude acid from 8000 grams of sodium perchlorate, consisting mainly of sodium salts, contained a little sulphate and a trace of phosphate, but the last 20 cc. of acid distilled from this showed no trace of phosphoric acid.

Since the acid was never distilled less than four times, each time rejecting a small residue, its purity was evidently quite beyond reproach. If further proof was needed, this was furnished by the fact that the residue of 5 cc., remaining after distilling off about 8500 grams of acid (previously twice distilled) and which must have contained practically all the sulphuric acid present in the entire amount, showed only the merest trace of it, not over 0.0001 gram.

Silver.—The preparation of pure silver has been fully described by Richards and Wells[1] and the details need not be repeated here. Four samples were prepared.

Sample A. Pure silver nitrate was recrystallized five times from dilute nitric acid, using vessels of Jena glass. The crystals were centrifugally drained in platinum funnels. The silver was then precipitated by ammonium formate, prepared from redistilled ammonia and formic acid, and after thorough washing, it was fused on pure lime in a current of dry hydrogen, generated by the action of "hydrone"[2] on water. The boat was provided with partitions, so that buttons of a suitable size were formed. These were etched with dilute nitric acid, washed, and dried in a vacuum at 400°.

Sample B was prepared in a similar way except that it was recrystallized twice in glass and four times in platinum, and the reduction with formate was conducted in a platinum dish.

Sample C was obtained by precipitating the mother liquors from A twice successively with formate, and then fusing on pure lime with a blast lamp.

Sample D was prepared from pure silver nitrate which had been once recrystallized, precipitated with formate, and fused on lime in hydrogen. This and sample C were used only as the source of silver nitrate in the precipitation of silver chloride to be weighed.

Experiments were made to determine whether the platinum dish was attacked by the hot nitric acid used to dissolve the silver nitrate, the dish being weighed before and after the operation. There was no loss in weight when the contents of the dish were stirred with a smooth glass rod, but when a platinum spatula was used, and the stirring was very vigorous, a loss of 0.24 mg. was observed, doubtless due to abrasion by its rather sharp edges. The precipitation of silver by formate caused no change in the weight of the dish.

Lithium Chloride.—The most common impurities in lithium salts and likewise the most difficult to eliminate are those elements most nearly related to it—the metals of the alkalies and alkaline earths. In the material which formed the source of the lithium chloride used in this work, the only impurities present in appreciable amounts were iron, calcium, potassium, sodium and probably magnesium. It is true that none of the latter was ever found, but this is probably due more to the difficulty of detecting small traces of it in the presence of large quantities of lithium, than to its entire absence. In Kahlbaum's lithium chloride, which formed part of the original material, no calcium, potassium or magnesium could be found. Since the iron was very easily removed, the impurities whose separation demanded careful investigation were potassium, sodium, calcium and magnesium. The relative effects of these on the atomic weight of lithium vary in the order given, that of potassium being the greatest.

---

[1] This Journal, 27, 472 (1905).

[2] This is the trade name for an alloy of sodium and lead.

Attention was first turned to the methods of eliminating potassium and sodium, which go together. Those employed by previous investigators were either inadequate or extremely wasteful. To the first class belongs that of dissolving the chloride or nitrate in a mixture of alcohol and ether. This was found to be effective in removing the greater part of the sodium from a crude chloride, especially if the solution were treated with hydrochloric acid gas until part of the lithium chloride was precipitated; but aside from this, it has no value. Precipitation by means of ammonium carbonate is effective, but the yield is very small, since only half of the lithium can be precipitated in one operation, owing to the solvent action of the ammonium salts. The conversion of the normal carbonate into bicarbonate demands too great a volume of solution, and is entirely too tedious where large quantities are required.

The most common method of purification—the recrystallization of soluble salts—seems to have received no attention, and accordingly various salts were tested with regard to their fitness for this purpose. With lithium chloride, the amount of sodium steadily decreased upon successive recrystallization until only a trace remained, but this trace was very hard to remove. Moreover, the solubility of the salt is so great that the process is very wasteful. The oxalate was almost useless in this respect. Recrystallization of the formate was fairly effective, but its electrolytic oxidation to carbonate was more so. Both the perchlorate and nitrate gave good yields, and the elimination of sodium was rapid, especially in the case of the nitrate. Care must be taken, however, to crystallize this latter salt below 29.6°, the transition point between the hydrated salts $LiNO_3.\frac{1}{2}H_2O$ and $LiNO_3.3H_2O$. Above 61° the anhydrous salt crystallizes, and under these conditions the separation from sodium is poor. The perchlorate crystallizes as $LiClO_4.3H_2O$.

These two salts were, therefore, selected as giving the most favorable results, but even with their help it is almost impossible to eliminate the last traces of sodium. It was evident that some method involving precipitation would be necessary. A search among the insoluble salts of lithium showed that the solubility of the fluoride is only 2.7 grams per liter—one-fifth that of the carbonate—and that this solubility is not appreciably affected by the presence of ammonium salts. Sodium fluoride is sixteen times, and potassium fluoride three hundred and forty times more soluble. Evidently the precipitation of lithium fluoride by ammonium fluoride ought therefore to be an extremely efficient means of removing sodium, without appreciable loss of lithium, and this was found to be true. Solutions of ammonium fluoride and of a lithium salt were run slowly into boiling water in a platinum dish, with constant stirring, taking care to avoid any great excess of either. The lithium fluoride formed under these conditions was coarsely crystalline and the precipitation was practically complete. The precipitate was transferred to platinum funnels and washed several times with water, using centrifugal drainage. Such washing has been shown to be very effective.[1] If the original material contained comparatively little sodium, this precipitate was found to be entirely free from it, upon careful spectroscopic examination, and a repetition of the precipitation was sufficient to attain this end, even with very crude material. The pure fluoride was then converted into either nitrate or perchlorate by heating in a platinum retort with the corresponding acid—the distillate when perchloric acid was used being pure hydrofluoric acid, which was used again. When nitric acid was used, three or four times the theoretical quantity was required, owing to the slight difference in the boiling points of the acids. Thus it was possible to obtain, rapidly and without appreciable loss, lithium nitrate or perchlorate absolutely free from sodium. Some difficulty was experienced when making the spectroscopic tests, in obtaining a flame free from sodium, but if the air of the room was not dusty, this could be accomplished by using a small blast flame, supplied with pure washed air.

This method does not, however, eliminate calcium and magnesium, since the fluorides of both these metals are less soluble than that of lithium. Previous treatment of the solution with lithium fluoride is not very effective, but the addition of ammonium oxalate removes nearly all the calcium. The addition of lithium carbonate is yet better, only traces of calcium and magnesium remaining. These may be wholly separated by the recrystallization of the nitrate or the perchlorate. From a sample of lithium nitrate to which had been added 10 per cent. each of lithium sulphate, and calcium and magnesium as nitrates, there was obtained after four recrystallizations a salt which gave no tests for any of these impurities. The recrystallization of the perchlorate was almost equally effective.

The method of purification finally adopted was, therefore, essentially the following: The fluoride, free from sodium but containing possible traces of calcium, magnesium, and sulphate, was converted into nitrate or perchlorate as described. These salts, free from fluorine, were recrystallized several times, using centrifugal drainage. The efficiency of this method may be shown by the fact that 70 grams of free acid were so completely removed from 400 grams of lithium perchlorate by three recrystallizations that less than a milligram of free acid remained. Since even in the mother liquors from the first recrystallization no calcium, magnesium, or sulphate could be detected by the ordinary tests, there is no doubt that this recrystallized nitrate or perchlorate was exceedingly pure. All silica must have been removed when the fluoride was dissolved in acid. The final step of this sequence of operations alone remained to be taken, namely, the conversion of the salts into chloride.

---

[1] Richards, This Journal, 27, 104 (1905).

In the case of the nitrate the conversion into chloride was not difficult. The solution was poured into a hot, concentrated solution of ammonium carbonate, which had been distilled in a platinum retort, and the precipitated lithium carbonate was washed several times with hot water, using centrifugal drainage. It is essential that hot and concentrated solutions be used; otherwise, the yield of carbonate—at best only 50 per cent.—will be much smaller. The precipitate is coarsely crystalline and easily washed. This process also serves as a means of further purification. The carbonate was dried at 300°, dissolved in slightly less than the theoretical amount of the purest hydrochloric acid which had been twice distilled and condensed and collected in quartz, and subsequently filtered from excess of carbonate. The solution contained a little nitrate, and to convert this into chloride without fear of attacking the platinum, a solution of pure hydrazine hydrate, distilled in platinum, was added, and then excess of hydrochloric acid. After boiling the solution a few minutes, all the nitrate was reduced, and there remained a solution of pure lithium chloride with a little hydrochloric acid and hydrazine chloride, both of which were completely volatilized in subsequent operations. The chloride was recrystallized once or twice, and dried, and it was then ready for analysis. During the purification it was treated only with materials prepared in quartz or platinum.

The conversion of lithium perchlorate into chloride was not so simple. At first the solution was mixed with ammonium chloride and the crystals of ammonium perchlorate were separated by filtration. The solution containing the lithium chloride was evaporated and ignited, but unfortunately, on ignition the small amount of perchlorate remaining caused the evolution of considerable chlorine, which attacked the platinum badly. If quartz was used, it also was attacked, the salt becoming alkaline. Careful ignition in platinum was the method finally adopted, the presence of the metal being decidedly the lesser evil; but it was necessary to regulate the temperature very carefully, otherwise the action became too violent. The chief action on the platinum occurs only towards the end of the operation, when a higher temperature was required. It was found advantageous to halt the operation at the point where the mass became pasty, to dissolve the product in water and evaporate to dryness, thus uniformly diluting the perchlorate with an excess of chloride. Sometimes chloride from a previous operation was added. If the final heating was performed in air, the platinum was always slightly attacked, but if this were done in an atmosphere of hydrogen, the slightly alkaline chloride could be fused without any appreciable effect on the vessel. The chloride thus prepared was freed from platinum and crystallized two or three times and was then ready for analysis. This method of preparation must have given a product absolutely free from traces of other halogens. In all the preparation work, exclusion of dust was the greatest difficulty. It was found desirable to shorten all the processes whenever this could be done, so as to expose the material as little as possible. The principal impurity introduced by dust is sodium. It seemed best, therefore, to effect the elimination of the last traces of sodium towards the end of the purification, rather than at the beginning.

Several samples of lithium chloride were prepared by these methods, platinum vessels being used throughout. The material which served for the preparation of sample A consisted of chloride prepared from commercial carbonate and freed from most of its sodium by treatment with alcohol and ether. It was recrystallized six times, precipitated as fluoride and added to another specimen of fluoride which had been precipitated from the mother liquors, twice recrystallized as perchlorate, and finally precipitated yet again as fluoride. Subsequently, it was all converted into perchlorate, twice recrystallized, treated with ammonium chloride to remove most of the perchlorate, and ignited in platinum. The platinum which was dissolved was removed by a solution of hydrazine, and the chloride was crystallized once more from hydrochloric acid solution. Owing to an accident in which most of it was lost, this sample was sufficient for only one analysis. It contained a barely visible trace of sodium.

Sample B was prepared from commercial lithium chloride, also purified by solution in alcohol and ether. The main portion was twice precipitated as fluoride. To this precipitate was added some fluoride precipitated from the last mother liquors of A, and the whole was converted into perchlorate, which was recrystallized three times. It was then treated with ammonium chloride, and finally fused in platinum. The platinum which was dissolved was removed as usual by precipitation with hydrazine, and the salt was evaporated to dryness. It also contained a trace of sodium.

Sample D. To the mother liquors from the last three recrystallizations of sample B were added some fairly pure residues of lithium chloride, and the whole was precipitated as fluoride. At this point it was free from sodium. After conversion into perchlorate it was recrystallized six times, ignited to chloride in platinum, fused in hydrogen, and twice recrystallized as chloride. This was D_3. The mother liquors from these two recrystallizations formed D_4. The mother liquors from the last three recrystallizations of the perchlorate were once recrystallized; the perchlorate was ignited to chloride and crystallized once. This was D_2. The mother liquor formed D_1. All these preparations contained a trace of sodium, in spite of the fact that previously the material had been free from this element, and no glass vessels had been used. The sodium undoubtedly came from traces of dust.

Sample C. Residues of lithium nitrate and bromide from other work on lithium were treated with ammonium oxalate to remove calcium, and twice precipitated as fluoride. The remainder of sample B was likewise precipitated as fluoride and added to this. All of it was free from sodium. It was converted into nitrate by evaporation in a platinum retort with the purest nitric acid and water, freshly distilled. After expelling all the acid, it was dissolved in water and filtered from a slight residue containing fluoride, and platinum. The solution contained no platinum, and was absolutely free from sodium. The nitrate was recrystallized three times, poured into freshly distilled ammonium carbonate, and the precipitate washed and dried. It was almost completely dissolved in the purest hydrochloric acid, filtered, more acid added, and then a little hydrazine hydrate. Boiling soon destroyed the nitrate present, and the pure chloride was crystallized once. At last, this sample was entirely free from sodium, and therefore was worthy to form the basis of some of our best experiments.

Sample E was prepared in much the same way as C. Two kilograms of Kahlbaum's best lithium chloride, nearly anhydrous, were available as raw material. Tested carefully, it showed no potassium, calcium or magnesium, and only small traces of iron, but as usual it contained considerable sodium. The salt was dissolved in about 8 liters of pure water, and agitated with pure lithium carbonate, being allowed to stand over night in large Jena flasks. The precipitate contained iron but no calcium. The perfectly clear, colorless solution after filtration was evaporated in a platinum dish, and crystallized with centrifugal draining, and the mother liquor was evaporated further, the second group of similarly drained crystals being added to the others. The whole was recrystallized, and treated again in the same way. In order to eliminate the small amount of sodium which still remained, the lithium was precipitated as fluoride. The coarse-grained, easily washed precipitate was collected upon a Büchner funnel, and was washed two or three times, being each time stirred up with the water. The washed material was whirled in the platinum centrifuge, and then washed six times, taking four milliliters of water each time, and draining completely with centrifugal action after each washing. The last wash water contained only a faint trace of chloride and the salt was found to be almost wholly free from sodium when examined in the spectroscope. In this way were obtained 620 grams of dry, very pure lithium fluoride, which served as a basis for yet further operations These successfully removed the traces of impurity still remaining, as the following description shows.

The coarse-grained powder was now decomposed by heating with a large excess of nitric acid in successive additions. About six times the theoretical quantity of 70 per cent. nitric acid was required in all, diluted with an equal bulk of water, it having been found that the diluted acid was more efficient than the concentrated acid. After the expulsion of the nitric acid, the nitrate was slightly alkaline, and no trace of platinum was found by the potassium iodide test in the filtrate, although the residual precipitate of lithium fluoride contained platinum. In order to be sure that no platinum was present, the clear filtrate was treated with a little hydrazine hydrate, but no change occurred All the nitrate was finally evaporated with excess of nitric acid until neutralized, and the nitrate was crystallized three times with centrifugal drainage in platinum. The trace of sodium present in the fluoride had now entirely been eliminated. The mother liquors from the last two crystallizations were evaporated and twice recrystallized again, yielding material free from sodium, like the other crystals to which they were added.

The lithium was now precipitated as carbonate—a process which rendered certain the elimination of any traces of fluoride which may have found its way through the successive recrystallizations of the nitrate.

The ammonium carbonate for this purpose was prepared by distilling the substance with water in a platinum still into a platinum dish. The solution was heated to the point of obvious decomposition and the lithium nitrate was then poured into it, the whole being digested for a time at a high temperature. The lithium carbonate was collected in platinum funnels, washed three times with hot water, using centrifugal drainage, and was dried at over 400° in an electric oven. Only about 250 grams of carbonate were thus obtained, a yield of less than 30 per cent. of the original fluoride.

The lithium carbonate was then dissolved in hydrochloric acid which had been twice distilled in quartz, rejecting the first and last portion each time. The solution was alkaline, because not quite enough acid had been added to correspond to the carbonate. The filtered solution was treated with a small amount of hydrazine hydrate and a considerable excess of hydrochloric acid. After evaporation, the solution which had originally given a strong test for nitrate with diphenylamine was found to be wholly free from this contamination. The purest water was now added, enough to make a hot saturated solution, and the substance was crystallized by cooling the platinum vessel in ice. The crystals were drained centrifugally in platinum and another crop was obtained from the mother liquor, and the combined material was redissolved and again recrystallized in the same way. In the least pure of the mother liquors an exceedingly faint trace of sodium was found, but the crystals after centrifugal drainage were entirely free from it as far as the most careful spectroscopic testing could show.

Most of the water was driven off from these crystals over the electric hot plate, and the stirred mass was heated in the electric oven at a high temperature until nearly all the ammonium chloride present had been volatilized. The mass weighed about 170 grams when dry, or about 17 per cent. of the lithium originally present as fluoride. A portion of this substance was broken into pieces in a clean warm agate mortar and used in Analyses 21-22, 30, and 31.

In spite of the fact that various methods had been used in these purifications, and the fact that some of them contained minute traces of common salt, the five preparations were all essentially identical, except from the point of view of the most critical experimenter. The maximum variation affected only the third decimal place in the atomic weight; the second figure was never in doubt. The two purest samples, which were wholly free from sodium, namely samples C and E, gave exactly the same result, within the limit of error of the experiments. This fact will become manifest when the detailed figures are presented, on pages 31 and 33.

The Drying and Weighing of the Lithium Chloride.

The final preparation of the salt for analysis consisted in expelling the last traces of water by fusion in a platinum boat in a current of dry hydrochloric acid gas and nitrogen, the operation being conducted in the apparatus usually used for this purpose at Harvard.[1] To avoid absorption of acid by the chloride, this gas was swept out by a current of pure nitrogen, before the salt solidified, and after cooling, the nitrogen was replaced by dry air. The boat was then transferred to the weighing bottle without contact with a trace of moisture, and weighed.

In the preliminary experiments the old form of "bottling apparatus"[1] was used for this purpose, but in the final series, the new form shown in Fig. 2 was employed.

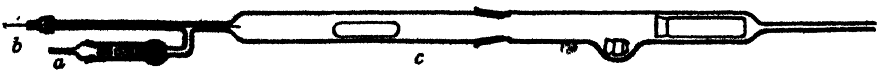

Fig. 2.

In this any possibility that moisture might gain access to the salt is excluded; the calcium chloride tube (*a*) is not removed and the glass rod used to push the boat into the bottle is passed through a short piece of rubber tubing at (*b*). When this apparatus was constructed of glass, evidence was found of the introduction of other alkali-metals into the lithium salt by the action of hydrochloric acid on the red hot tube. Hence in the final experiments, this portion of the apparatus (*a* to *c*) was made entirely of transparent quartz, and carefully ground into the other. The tube was heated by winding it with "nichrome" ribbon, through which a suitable current was passed, an arrangement that not only gave evenly distributed heat, but also allowed the progress of the fusion to be clearly observed. The apparatus was so constructed that by turning the proper stopcocks, either hydrochloric acid, nitrogen, air, or any desired mixture, could be passed through it. These stopcocks were so carefully polished with rouge that a trace of lubricant composed of a mixture of paraffin and pure rubber made them perfectly gas-tight.

---

[1] Richards and Parker, *Proc. Amer. Acad.*, 32, 59 (1896).

The nitrogen was prepared by passing air charged with ammonia over red-hot copper. Carbon dioxide was removed by means of potassium hydroxide solution, and the excess of ammonia, by passing the gas through a series of towers filled with glass beads moistened with sulphuric acid, the first two containing dilute, and the last three, concentrated acid. The last traces of water were removed by means of resublimed phosphorus pentoxide. Nitrogen prepared in this way usually contains a trace of hydrogen, which in this case was a distinct advantage, since it would counteract the effect on the platinum boat of any trace of oxygen that might be present.

The hydrochloric acid gas was prepared by dropping concentrated sulphuric acid into a solution of pure concentrated hydrochloric acid. It was dried by passing through three towers filled with pearls moistened with freshly boiled concentrated sulphuric acid, for it has been shown[1] that phosphorus pentoxide is unsuitable for this purpose. No sulphuric acid could be detected in the solution obtained by passing into water a large quantity of the gas thus prepared.[2]

The air, which was furnished by a water pump, was purified by passing successively through towers containing potassium hydroxide, silver nitrate and concentrated sulphuric acid, and was finally dried by phosphorus pentoxide. The entire apparatus was of glass, the different parts being fused together, when possible, or else connected by carefully ground joints.

In detail the procedure was as follows: Dry lithium chloride contained in the platinum boat, was placed in the quartz tube and a mixture of nitrogen and hydrochloric acid passed through it for an hour or two, in order to sweep out all the oxygen. The gases issued under slight pressure, the end of the exit tube dipping just below the surface of mercury, covered with water to absorb the acid. The temperature was very slowly raised so as to expel from the salt as much water as possible before fusion. The chloride was maintained in a state of fusion at a red heat from fifteen to thirty minutes, the longer time apparently causing no further change. During this time the surrounding gas consisted principally of dry hydrochloric acid. Bubbles always formed on the bottom of the boat and were removed only by carefully shaking the tube. The hydrochloric acid was then replaced by pure nitrogen, to remove any excess of acid dissolved in the fused salt, and when the issuing gas was neutral, the chloride was allowed to cool. It was quite transparent and colorless. Because fused sodium chloride was found to be essentially free from dissolved nitrogen,[1] it is reasonable to assume that the similar lithium salt contained no weighable quantity. After the nitrogen had been replaced by dry air, the boat was bottled and placed in a desiccator. No great difficulty was experienced in obtaining weighings agreeing within 0.02 mg., using a similar bottle as counterpoise. Of course the bottle containing the empty boat was always filled with dry air before being weighed. The platinum boat was always weighed separately before and after the fusion, and the loss in weight, if the operation had been carefully conducted, was only a few hundredths of a milligram—sometimes none at all. This correction, if added to the weight of silver chloride, had no appreciable effect on the results.

---

[1] Baxter and Hines, THIS JOURNAL, 28, 779 (1906).

[2] See also Baxter and Hines, *Loc. cit.*, p. 780.

The boat was placed in a three-liter Erlenmeyer flask of Jena glass, with a carefully ground and polished stopper, and about 0.05 or 0.08 liter of water was added. When the chloride was dissolved, the solution was perfectly clear, and it was usually tested for alkalinity by adding a very dilute solution of phenolphthalein, which had been colored very faintly pink by a trace of sodium hydroxide. It is not sufficient to add a colorless solution of the indicator, for the ever-present trace of carbon dioxide decreases the delicacy of the test. The color never became deeper, and on thorough shaking was discharged by the carbon dioxide. Methyl orange showed a perfectly neutral tint. There can be no doubt, therefore, concerning the neutrality of the salt within the narrow limits thus established. About one liter of freshly distilled water was then added to the flask; the boat was lifted out by means of a heavy platinum wire, bent at one end, and was washed seven times in a beaker, the washings being completely transferred to the flask. This method seemed preferable to dissolving the salt in a beaker and transferring it to the flask, for not more than a few milligrams of lithium chloride could have remained on the boat when it was lifted out, and this small quantity could be transferred without any risk of loss.

---

[1] Richards and Wells, THIS JOURNAL, 27, 513 (1905).

The lithium chloride was then ready for analysis. Both of the familiar methods for finding the amount of chlorine were used, namely, the weighing of the precipitated silver chloride on the one hand, and the determination of the necessary amount of silver on the other. These are discussed below in order.

The Precipitation and Weighing of Silver Chloride.

The precipitation of the silver chloride and all subsequent operations were carried out under red light in the dark room. To the solution of lithium chloride was added exactly the calculated amount of silver dissolved in a moderate excess of nitric acid, the concentrations of the solutions being about decinormal. The mixture was shaken vigorously for ten minutes and allowed to stand over night. The next day it was again shaken, and to it was added the excess of silver nitrate required for complete precipitation—about 0.05 or 0.06 gram of silver per liter. This method diminishes greatly the danger of occlusion of silver nitrate, as Richards and Staehler have shown.[1] The solution was shaken from time to time during the next day, and after standing until the supernatant liquid was perfectly clear, it was ready for filtration.

In a few of the preliminary experiments, the Gooch perforated platinum crucible with asbestos mat was used, with all the precautions previously adopted in this laboratory. In all others a Gooch-Munroe crucible[2] was used. The complete removal of silver chloride from the platinum sponge, when preparing for a new analysis, required treatment with concentrated ammonia for at least twelve hours, followed by a very thorough washing. The crucible was always dried over night at 250°, and a perforated platinum plate was placed upon the sponge to prevent rupture by the contraction of the silver chloride as it dried. This crucible was of the special shape recently described by one of us.[3]

The clear solution was poured through the crucible, and the precipitate was washed four times by decantation with a cold acid solution of silver nitrate, about two-hundredths normal, the precipitate being thoroughly agitated by rotary shaking each time. The filtrate and washings were united and were always practically free from excess of chlorine, so that a constant correction of 0.04 mg. of silver chloride per liter was applied to them.[4] The precipitate was then washed ten times with very dilute nitric acid, cooled in ice to reduce the solubility of silver chloride, and finally transferred to the crucible by means of a jet of pure, cold water from a hydrostatic wash-bottle. The entire process was conducted under a clean pane of glass to prevent dust from falling into the crucible. The latter was finally wiped with a clean cloth and heated in an electric oven, gradually increasing the temperature to 250°, where it was maintained at least ten hours. After it had been weighed, the main mass of silver chloride was separated from the platinum disk and fused in a covered quartz crucible contained in a larger one of porcelain. Since the cover was transparent, it was possible to free the fused chloride from the bubbles which invariably adhered to the crucible, without danger of loss from spattering, by carefully rotating the crucible. With one or two exceptions, the fused silver chloride was perfectly colorless and transparent, showing the absence of organic dust and occluded silver nitrate. The loss on fusion was very small, never more than a few hundredths of a milligram per gram. The correction for the entire weight of silver chloride was calculated as usual from that of the portion fused, always over 90 per cent. of the total.

The flask was carefully rinsed out with ammonia, to remove any chloride that might have escaped observation. This with the washings, was tested as follows: To the total washings, exclusive of those with dilute silver nitrate, was added 0.07 gram of silver as nitrate, and after the opalescence had appeared, it was dissolved by pouring in the ammoniacal rinsings. The volume was then made up to one liter. A standard solution was prepared, containing in one liter a known amount of chloride, and the same quantity of ammonia and of silver present in the washings. Twenty-five cc. of each solution were pipetted into a nephelometer[1] tube, 2 cc. of dilute nitric acid added to each and the contents stirred with a carefully cleaned glass stirrer. The tubes were covered with glass caps having a plane top, and allowed to stand from three to five hours, until constancy was attained. If the tubes were not nearly alike, a new standard was prepared. Several comparisons were always made and found to agree within reasonable limits of error only when extreme care was used in preparing the solutions and in excluding dust. By the use of ice-cold wash water, the total nephelometer correction was reduced from over 1 mg. to about 0.35 mg., often less, owing to the decrease in solubility of silver chloride. This matter will subsequently be discussed in detail.

The following table gives the results obtained in the preliminary experiments.

The first two analyses have little value since the technique of the process had not then been mastered and the material was purified only by six recrystallizations as chloride, and was known to contain impurities. No. 10 was rejected because it was found that all the silver chloride from the previous analysis had not been dissolved out of the Munroe crucible.

RATIO OF LITHIUM CHLORIDE TO SILVER CHLORIDE.

Preliminary Series.

No. of analysis.	Preparation of LiCl.	Weight of fused LiCl, vacuum.	Weight of fused AgCl, vacuum.	$\frac{LiCl}{AgCl}$.	Atomic weight of Li. Ag = 107.88.
1	O	4.01994	13.59125	0.295774	6.938
2	O	6.32840	21.39635	0.295770	6.939
3	A	8.99620	30.41341	0.295797	6.942
4	B	4.66824	15.78111	0.295812	6.944
5	B	5.43032	18.35734	0.295812	6.944
6	B	5.10725	17.26504	0.295815	6.944
8	D_1	5.74000	19.40375	0.295819	6.945
9	D_2	5.42038	18.32417	0.295805	6.943
11	D_3	5.21573	17.63280	0.295797	6.942
12	D_4	6.56925	22.20716	0.295817	6.945
13	D_8	4.84268	16.37121	0.295805	6.943
					6.943

In none of these analyses was the material wholly above reproach, for it all contained traces of sodium. Part of this impurity was present in the original salt, and those specimens (A and D_3) which show less sodium in the spectroscope gave a lower value for the atomic weight. Part of the sodium, however, may perhaps have come from the glass tube used to contain the boat in which the lithium chloride was fused. This conclusion was drawn from the fact that material thus fused showed in the spectroscope more sodium than it had possessed before. Nevertheless, these preliminary results are far nearer the truth than the work of any other experimenter.

In order to avoid the vitiating circumstances every conceivable precaution was taken in the final series recorded below. Both the samples of lithium chloride used were proved to be free from any visible trace of sodium discernible upon careful spectroscopic examination. This means, of course, a very high degree of purity. Moreover, the platinum boat during the fusion of the salt was contained in a tube of pure quartz. In this way only can a pure dry sample of lithium chloride be obtained, which will show no trace of sodium in the spectroscope.

As a result of these precautions the values of the atomic weight obtained were appreciably lower than those of the preliminary series, and they agreed distinctly better among themselves. The following table explains itself.

Analyses 19 and 20 were omitted because of accidents which rendered them valueless. Experiments 14 to 17 inclusive had previously been used for determining the weight of silver needed for the exact precipitation. This part of these experiments is recorded in the table on page 33, under the numbers 26 to 29.

RATIO OF LITHIUM CHLORIDE TO SILVER CHLORIDE.

Final Series.

No of analysis.	Preparation of LiCl.	Weight of fused LiCl, vacuum.	Weight of fused AgCl, vacuum.	$\frac{LiCl}{AgCl}$.	Atomic weight of Li. Ag = 107.880.
14	C	6.28662	21.25442	0.295779	6.9391
15	C	5.82076	19.67873	0.295790	6.9407
16	C	6.70863	22.68030	0.295791	6.9409
17	C	6.24717	21.12073	0.295784	6.9399
18	C	5.50051	18.59600	0.295790	6.9407
21	E	8.34521	28.21438	0.295779	6.9391
22	E	6.65987	22.51564	0.295789	6.9406
		45.56877	154.06020	Av. = 0.295786	6.9401

Comparison of these results is highly interesting, and leaves no doubt concerning the atomic weight of lithium. The average result for the atomic weight of lithium, computed from these final results taken together, is 6.9401, with a "probable error" of 0.0002.

It is pleasing to note that the average, 6.9403 of experiments 14 to 18 inclusive, made with sample C of lithium chloride is almost identical with the average 6.9399 of experiments 21 to 22 made with Sample E. The difference between the averages is only 0.0004, and the average of the first five lies between the values given by the last two experiments. The extreme range is only from 6.939 to 6.941, whereas the extreme range in the preliminary series was from 6.938 to 6.945.

The agreement of these two samples made from different raw materials and purified in somewhat different ways seems to leave no doubt concerning the validity of the result except insofar as constant errors in the methods of analysis or constant unavoidable impurities are concerned. The former of these causes of uncertainty is rendered highly improbable by the next series of experiments, to which attention is now directed.

The Ratio of Lithium Chloride to Silver.

A single series of experiments is never convincing in work of this kind; accordingly the preceding determinations were supplemented by others, which determined the exact amount of silver necessary to precipitate the chlorine in weighed amounts of lithium chloride. No important difference in the final value was expected, because sodium and potassium showed none under similar conditions, but the further work had the advantage of making "assurance doubly sure."

In this series of experiments weights of the purest silver, equivalent to those of the lithium chloride, as calculated from the preceding table, were dissolved in nitric acid in a Jena flask provided with a tower of bulbs to prevent loss by spattering. Almost the exact amount of silver could be weighed out directly, by selecting suitable pieces from a large assortment of very fine globules; and the last few hundredths of a milligram were added, if necessary, in the form of a standard solution, prepared from the same silver. The solution of silver nitrate was diluted to about 1 liter and added to the solution of lithium chloride exactly as in the preceding series. Great care was used to transfer every trace of silver from the flask. After standing for a day or two, with occasional violent shaking, the presence of an excess of silver or of chlorine was then determined with the nephelometer, following the procedure adopted by Richards and Wells.[1]

One very important innovation was introduced. The accuracy with which the end-point can be determined by this method is almost inversely proportional to the concentration of the silver halide remaining in solution, because the percentage accuracy of the nephelometer does not increase with increasing cloudiness. It has long been recognized that the titration of bromides is more exact than that of chlorides, because the solubility of silver bromide is less than one-tenth of that of the chloride. These considerations show that any means of decreasing the solubility of silver chloride will increase the precision of the end-point. The solubility of silver chloride in water changes greatly with the temperature,[2] being over four times as great at 34° as it is at 1.5°. It seemed worth while, therefore, to try the effect of cooling the solution in ice. Analysis 3 was made to test this point. At this time the weather was quite warm, the temperature sometimes rising above 30°. The solubility was tested on fourteen successive days, the flask being shaken each day. It was found to vary from 2.2 mg. to 3.4 mg. per liter; the presence of nitric acid was undoubtedly responsible for a higher average value than Kohlrausch's. Opalescences produced by the precipitation of the chloride in such a solution are so intense that it is difficult to estimate accurately their contents in the nephelometer. The flask was then packed in ice, and the solubility again determined for several days. It became very constant, varying from 0.5 to 0.6 mg. per liter. Most of the values obtained were about 0 5 mg., a figure which begins to be comparable with that for silver bromide at ordinary temperature—0.10 mg. The opalescences were so faint that the slightest excess of silver or of chlorine was unmistakably evident. Richards and Wells estimated that they could detect a difference of 0.02 mg. of silver per liter; this limit we have doubtless reduced by cooling. Assuming the weight of lithium chloride to have been accurate to within 0.02 mg., there could not have been an error exceeding 0.05 mg. in the weight of silver, since the total volume was only two and one-half liters. The determination by this new method of the weight of silver required is evidently the most accurate part of the analysis, and the cause of the variation in results must be sought elsewhere. There is moreover another advantage in this method. Since the concentration of silver chloride in solution is constant, at the constant low temperature, it is possible to calculate with greater exactness than before the amount of a deficiency of either silver or chloride, in terms of the ratio of lengths of the two nephelometer columns giving equal apparent opalescences. This advantage hastens the work.

---

[1] This Journal, 27, 502 (1905).

[2] Kohlrausch, *Z. physik. Chem.*, 64, 148 (1908).

Only two preliminary experiments were made, for the technique required by the determination is so simple that it is readily mastered. The results of these two preliminary experiments, made with material not perfectly free from sodium, are given below:

RATIO OF LITHIUM CHLORIDE TO SILVER.

Preliminary Series.

No of experiment.	Continuation of analysis.	Preparation of LiCl.	Wt fused LiCl, vacuum.	Wt. of Ag, vacuum.	$\frac{\text{LiCl}}{\text{Ag}}$.	Atomic wt. of Li. Ag = 107.88.
23	3	A	8.99620	22.89013	0.393017	6.942
24	7	B	5.25395	13.36777	0.393030	6.943
				Average,	0.393023	6.942

The results agree almost exactly with the preliminary experiments made by the other method with similar material, as may be seen by referring to the first table on page 30. As has been said, these preliminary experiments are, of course, entirely neglected in this comparison of final results. All of the preparations used in this preliminary work contained traces of sodium, which would, of course, raise the apparent atomic weight of lithium; and accordingly these early values if included in the calculation would introduce a source of error. The experiments were, nevertheless, of great value to the investigators in the course of the work; therefore they seemed worthy of brief notice.

After the various processes had been mastered, the final series, using utmost care to exclude all sources of error, was undertaken. The exper-

29	17	C	6.24717	15.89620	0.392998	6.9397
30	..	C	7.75349	19.72977	0.392984	6.9382
31	..	E	7.99108	20.33415	0.392988	6.9386
			46.63197	118.65894	0.392992	6.9390

iments were consecutive. The method is simple, and accident easily avoided. Four experiments (Nos. 26 to 29 inclusive) were utilized further by weighing the precipitated silver chloride. This portion of the experiment received in each case another number, and the results are given as experiments 14 to 17 inclusive in the table on page 31.

These experiments then point to the number 6.9390 as the atomic weight of lithium, a number possessing a so-called "probable error" of less than 0.0002. It will be observed that the maximum deviation from the mean of all the experiments was less than 0.001 in the atomic weight of lithium, a quantity which corresponds to only about one part in 65,000 of the lithium chloride. This is about as high a grade of accuracy as has usually been attained in atomic weight work. It means about one-tenth of a milligram in weight of the substance taken, although the error is probably not to be traced to the work but rather to inevitable complications in the chemical part of the various processes, especially to occlusion of soluble salts by the silver chloride.

Discussion of the Final Results.

Thus two final results have been obtained for the atomic weight of lithium, namely, 6.940 by reference to silver chloride, and 6.939 by reference to pure silver. The close agreement of these values is important evidence of their verity, and there seems to be no doubt that the value 6.94 may be taken with great certainty as representing the true atomic weight of this lightest of the metals, supposing that silver is called 107.88. A change of 0.01 in the atomic weight of silver causes a corresponding change of only 0.0006 in that of lithium.

The reasons for the higher atomic weight found by other experimenters are not far to seek. Stas admitted that his lithium chloride was alkaline, a circumstance which would, of course, have raised the apparent atomic weight, and it is probable that further error was introduced by other impurities. Judging from the difficulties encountered in the present work, his methods of purification must have been entirely inadequate. In those cases in the work of others where the approximately correct value of lithium had been found, the fortunate result must be attributed rather to a compensation of errors than to any special excellence.

The fact that the two series of results gave essentially the same atomic weight of lithium shows that they indicate very nearly the same atomic weight of chlorine, referred to silver, as that found in the work of Richards and Wells. The average of the present work shows that one part of pure silver would give $\frac{0.392992}{0.295786} = 1.32864$ parts of chloride, while Richards and Wells obtained 1.32867. This shows that the silver must have been pure within one part in forty thousand, a fraction about equal to the experimental error of the analysis. One pair of experiments, namely the pair numbered 16 and 28, gave exactly the value found by Richards and Wells.

Another method of comparing these results is to reduce them both to the ratio of lithium chloride to silver. On this basis, if one part of silver chloride corresponds to 0.295786 of lithium chloride, and one part of silver corresponds to 1.32867 parts of silver chloride,[1] then one part of silver must correspond to 0.393002 part of lithium chloride. This obviously differs by one part in 40,000 from the result 0.392992 found directly. The mean of these two figures, namely 0.392997, may perhaps be supposed to represent the true value of the ratio to within one part in 80,000. This value will be chosen for the computation involved in the subsequent work.

Summary.

In conclusion of the first part of the work, the following brief summary presents the chief features. Lithium salts were in the first place studied with great care in order to discover the most suitable substance for the investigation and the best methods of purifying them. The precipitation of lithium as fluoride and the conversion of this precipitate into nitrate or perchlorate with many recrystallizations of the soluble salts was found to be the surest method of eliminating impurities, especially sodium. The perchlorate was decomposed by heat; the nitrate precipitated by ammonium carbonate in order to convert it into chloride. The purer the material the lower was the observed atomic weight of lithium, and the two purest samples gave precisely the same results within the limit of error of experimentation. In all 46.56877 grams of lithium chloride yielded 154.0602 grams of silver chloride, corresponding to 6.940 as the atomic weight of lithium. Moreover, 46.63197 grams of lithium chloride were found exactly to precipitate 118.65894 grams of silver, corresponding to the value for the atomic weight 6.939. These essentially identical results may be taken to represent the atomic weight of lithium, if silver is taken with the International Committee to be 107.88. If each of these results is given equal weight and 100.000 parts of silver are assumed to produce 132.867 parts of silver chloride, the corresponding amount of lithium chloride is 39.2997 parts.

PART II.—THE RATIO OF OXYGEN TO LITHIUM CHLORIDE.

Preliminary Experiments.

The reasons which led to the selection of lithium perchlorate as the salt to be used in determining the ratio between oxygen and silver, and the advantages of this substance, have already been mentioned briefly in the introduction. Part I of this paper[1] has described the determination of the atomic weight of lithium—an essential link in the chain of data.

---

[1] Richards and Wells, *Publ. Carnegie Inst. of Washington*, 28, 65 (1905).

After lithium perchlorate had been found to be susceptible of fusion without decomposition—thus being rendered anhydrous and suitable for accurate weighing—a method had to be devised for obtaining experimentally the ratio of perchlorate to chloride, and hence the ratio of oxygen to the chloride and to metallic silver.

Naturally, the first attempts were directed toward the quantitative conversion of perchlorate into chloride. Simple ignition first suggested itself, but was quickly abandoned, because this process involves a loss of chloride, unless extraordinary precautions are taken. The oxygen evolved carries with it particles of the salt so extremely minute that they color a flame fifteen or twenty feet distant, if the operation is performed in an open dish. To retain this dust would require such an elaborate apparatus that accurate weighing would be out of the question.

A means of reducing the perchlorate was then sought, which would prevent this evolution of oxygen, but this proved futile, for, as Kreider has shown,[2] perchloric acid is, in combination, one of the most stable of the oxygen acids, and is hardly affected even by the strongest reducing agents. Hydrogen is entirely without action on the fused salt at 300°, and hydrochloric acid was found to displace only very little of the perchloric. In aqueous solution the situation is not much more promising. Although chlorates in solution are readily reduced, perchlorates under the same conditions are almost entirely unaffected by the most powerful reducing agents, with the exception of ferrous hydroxide and titanous salts, which, in large excess, and upon long boiling, reduce them to chlorides.[3] This method is, however, quite unsuitable for precise work. All attempts to convert perchlorate into chloride, therefore, had to be abandoned, and the reverse process was considered.

The vapor from a constant-boiling mixture of perchloric acid and water, both alone and mixed with additional steam, was passed over lithium chloride at different temperatures; but although some hydrochloric acid was expelled, the conversion into perchlorate was only partial. Frothing and creeping occurred, with unavoidable loss of material. The anhydrous acid was not tried, for its use is highly inconvenient or even dangerous; and after an examination of the thermochemical relations involved, there was no reason for supposing that it would be any more effective than its hydrate, which has a higher boiling point. Recourse was had, therefore, to a method similar to that used by Richards and

---

Forbes[1] in the synthesis of silver nitrate. Lithium chloride was dissolved in water in a quartz flask, a slight excess of perchloric acid was added, over and above the amount needed to convert the salt wholly into perchlorate, and the solution was evaporated by allowing a current of air to pass through the flask, the temperature being regulated so that no ebullition occurred. The hydrochloric acid was soon expelled, and by gradually raising the temperature the excess of perchloric acid was volatilized, leaving pure, fused lithium perchlorate. The substances in the flask were thus changed gradually from a solution of the chloride into pure fused perchlorate, without the formation of a single bubble of gas or vapor. Hence the process is capable of the greatest accuracy.

Further experiments, planned in order to test details of the operation, showed that pure, neutral perchlorate, prepared by recrystallization, could be heated to 300° without decomposition. On the other hand, the salt formed in the above process always contained a trace of chloride and chlorate—as shown by its giving off oxides of chlorine when moistened with perchloric acid. This small amount, however, did not increase on further heating—a fact which indicated that it must have been formed during the evaporation of the excess of acid. This train of circumstances suggested that the impurities might be due to a decomposition of the last traces of acid, which are evolved only at a high temperature and in a nearly anhydrous condition. Since the anhydrous acid decomposes readily, while the dihydrate is very stable, it seemed reasonable to suppose that if the last traces of acid were removed at the lowest possible temperature, and in a current of air saturated with moisture (to prevent the dissociation of the dihydrate), this decomposition ought to be prevented, and a salt almost, if not quite, free from chloride obtained. This was found to be true. The purity of the perchlorate obtained depends upon the care with which the excess of acid is expelled before the temperature attains a high point.

The Conversion of Lithium Chloride into Perchlorate.

The determination of the ratio of lithium chloride to oxygen thus resolved itself into the following processes: Lithium chloride was to be fused and weighed in a boat just as described in Part I; it was then to be dissolved in a slight excess of perchloric acid; the hydrochloric and perchloric acids were to be driven out by steam; and the fused perchlorate was to be dried at 300° and finally weighed. The gain in weight of the salt is caused by oxygen alone and gives at once the ratio O_4 : LiCl. From the known ratio of lithium chloride to silver, the atomic weight of the last-named element is to be calculated.

The general method having been indicated, the complete details of the operation and the apparatus used will now be described. The preparation of very pure perchloric acid and lithium chloride has been already discussed in Part I.

---

[1] THIS JOURNAL, 29, 808 (1907).

The quartz flasks, of 100 cc. capacity, which served to conduct the quantitative evaporation, were made especially for the work of Heraeus. They are shown in cross section in Figures 3 and 4, and may be called evaporating flasks.

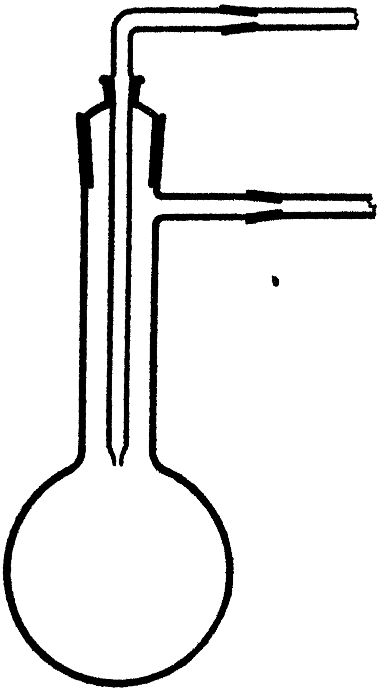

Fig. 3.

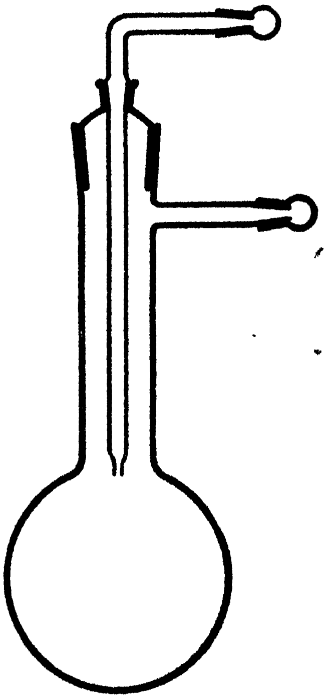

Fig. 4.

The quartz stopper was provided with a ground joint, into which fitted the bent quartz delivery tube. This tube could be removed and replaced by a small quartz stopper if desired. The ends of the delivery and exit tubes were ground to fit glass tubes (as in Fig. 3), which were attached during the evaporation, and after the operation was finished, were replaced by glass caps, which effectually closed the flask (Fig. 4). A loop of platinum wire fastened around the neck of the flask served to suspend it from the balance while it was being weighed. One of the flasks was used as a counterpoise. They were kept in separate large Hempel desiccators, with sticks of potassium hydroxide, and supported on baskets of platinum wire. Before weighing the empty flask it was always heated to 300° and dry air was passed through it for a short time, in order to remove any adsorbed moisture, and the flask then allowed to cool in a desiccator. As a matter of fact, experiment showed the same weight was obtained if the flask was filled with dry air at the ordinary temperature, but as a precaution it was always heated.

Platinum seemed to accelerate the decomposition of perchlorate by heat, as might have been expected, and the presence of this metal was, therefore, to be avoided. Hence it seemed desirable to fuse the lithium chloride, the accurately weighed factor in the reaction, in a quartz boat, which could then be left in the evaporating flask during the subsequent conversion to perchlorate. The troublesome transfer of its contents would thus be avoided. Careful quantitative experiments showed the lithium chloride could be fused in quartz in a current of hydrochloric acid without attacking the boat in the least, but unless the walls were very strong, it was cracked by the contraction of the fused salt as it cooled. A heavy-walled boat meant a smaller capacity for the fused chloride, and since it was desired to employ the maximum possible amount, the use of quartz was abandoned. A boat of platinum-iridium was especially made to fit into the flask, and used thereafter for the fusion of the lithium chloride. At one end was a slight projection provided with a hole, through which was passed the platinum wire that served to lower the boat into the flask.

The fusion and weighing of the lithium chloride have already been described in the first part of this paper, and need only be referred to here. The boat containing the fused and carefully weighed chloride was lowered gently into the neck of the evaporating flask to which had just been added a few cubic centimeters of purest water direct from the still. The flask, with the boat suspended in the neck, was placed over an electric heater, covered by a large bell-jar and kept warm over night. The aqueous vapor condensing on the chloride dissolved it, and the solution flowed down into the bulb of the flask. If time were an object, the boat was lowered directly into the water and the contents dissolved in a few minutes, but this method required more water than the other. In either case the final washing was accomplished as follows: To a wash-bottle was attached a glass tube terminating in a capillary, bent sharply at the end at right angles and cut off so close that it was very little thicker than the rest of the capillary and could be passed between the boat and the walls of the flask. By means of this fine horizontal jet of water, the boat could be washed on all sides and within. Since the wash-bottle was of Jena glass, and the water was allowed to remain in it only a few minutes, no appreciable amount of alkali could have been introduced in this way.

The boat was then lifted out and carefully rinsed in a beaker, the washings being tested in the nephelometer for chloride. The amount found was never more than a few hundredths of a milligram. This correction, when appreciable, was applied to the weight of lithium chloride.

A slight excess of the purest perchloric acid, which had been condensed and collected entirely in quartz, was now added. The contents of the evaporating flask were thoroughly mixed, and the flask was placed on a support of platinum wire in an electric oven. The oven was made especially for this purpose by winding a three-liter beaker with resistance ribbon, a window being provided through which the flask within could be observed. The stopper and delivery tube were inserted into the flask, and the delivery tube was connected by a ground joint with the source of moist air. The exit tube, passing through a hole in the side of the oven, was connected with a water pump to remove the acid vapors. The oven was provided with a glass cover, suitably perforated to admit the thermometer and the delivery tube.

The air, supplied by a water pump, was purified by passing successively through towers, some containing potassium hydroxide solution with a little manganate, and others containing a fifty per cent. solution of phosphoric acid, to which had been added potassium permanganate. Thus the air was freed from soluble impurities.

When dry air was desired, the current was passed through further tubes containing, respectively, fused potassium hydroxide and resublimed phosphorus pentoxide. When moist air was desired, it was passed through an electrically heated gas washing bottle containing water. By turning the proper stopcocks either moist or dry air could be passed into the evaporating flask. To prevent the condensation of water in the tube, the latter was wound with resistance wire from the bottle as far as the point connecting it with the quartz flask, and heated by the passage of a suitable current. The temperature of the oven containing the evaporating perchlorate solution was read on a thermometer, the bulb of which was placed in contact with the evaporating flask as close to the fused salt as possible.

The temperature of the oven was kept at 130° while dry air passed through the flask until about two-thirds of the water had evaporated; then it was raised to 150° until most of the hydrochloric acid had been expelled. Moist air was at this stage passed through the evaporating flask, and soon perchloric acid was evolved. After several hours at 160° no more appeared; at 180° a little more was expelled, and from this point the temperature was slowly raised to 250°. The salt was then neutral but not quite anhydrous. To remove the last traces of water, it was heated in dry air at 280–300° for at least five hours; further heating was found to cause no diminution in weight. The entire operation usually occupied three days. The perchlorate was allowed to cool in the current of dry air, until the crystals began to appear. It was then warmed to the freezing point (236°) and allowed to cool very slowly, so as to avoid too violent solidification. It was quite crystalline and transparent. The glass caps were then placed over the ends of the tubes and the flask was quickly removed to the desiccator, which was placed for a sufficient time beside the balance case in a room kept at nearly constant temperature.

The possibility that solid material which ought to be weighed might be carried away with escaping gas and vapor during the evaporation was duly considered. Experiments already made with silver nitrate[1] make it unlikely that this was the case. The method of evaporation seems to be really quantitative. Nevertheless, although no mechanical loss is apparent, there is a conceivable possibility that traces of the lithium perchlorate might be carried away in the state of vapor with the escaping perchloric acid or water at the high temperature. Unlikely as this might seem, it is nevertheless worth testing, and the test was easily applied by adding perchloric acid and water after the fused substance had been weighed and then repeating the evaporation, fusion, and weighing. The interpretation is somewhat complicated by the fact that the true weight of perchlorate can never be attained with perfect accuracy until one knows how large an amount of chloride and chlorate have been formed during the fusion. Rarely were these impurities wholly absent. Nevertheless, the following test is fairly satisfactory.

A neutral solution of nearly 14 grams of pure lithium perchlorate, after various preliminary trials in order to find the best succession of temperatures for the evaporation, was treated with a few drops of an excess of perchloric acid, and the acid was evaporated at 165° for several hours until the mass solidified. The temperature was now raised to 200° and kept there until the mass which had partially melted had again solidified; again gradually raised to 245°, and kept there for less than two hours; yet once more gradually raised to 280° where it was kept for five hours, and finally to 300° for yet three hours more. After making the correction to vacuum, the lithium perchlorate was found to weigh 13.92425 grams. It was then heated to 300° for five hours more and lost 0.00025 gram. This loss was due to loss of oxygen, however, as shown by the fact that on adding dilute perchloric acid a pale yellow solution was obtained. This was again evaporated rapidly at about 210°. Gradually the temperature was raised to 240° and was kept there until the excess of acid had been expelled and was then heated to 300° for three hours. The weight was now 13.92419, or only 0.00006 less than the first weight. As the heating had been brief, it was continued at about 300° for four hours more, when the weight was found to be 13.92416, essentially the same as before. Upon being dissolved in very dilute perchloric acid no trace of yellow color was observable, showing that the substance this time had not been greatly decomposed. Nevertheless, in order to test the matter yet again, the fused salt was dissolved in very dilute perchloric acid once more.

---

[1] THIS JOURNAL, 29, 815 (1907).

The water and perchloric acid were driven off as before, and the residual salt was dried three and a half hours at 300°. This time again the weight had changed only one-thirtieth of a milligram, being 13.92413 grams; and upon dissolving in dilute acid no trace of yellow color was to be perceived. Thus the total loss in two evaporations amounted to only 0.00012 gram, or an average of about one-twentieth of a milligram for each evaporation. This small loss is negligible, being only 1 part in 200,000 of the weight of material in question, and even this may be due to nothing more than a slightly greater loss of oxygen before the last weighing than before the first. An accident prevented the determination of the amount of chloride in the final sample. In the carefully finished determinations given in the final table the amount of oxygen lost varied from 0.00009 gram to 0.00078 gram, or on the average about 0.0004 gram. This is considerably more than the divergence between the weights given above, and therefore it is clear that the agreement noted above is as good as could be expected, and shows that no important amount of material is carried away with the stream of vapor and air during evaporation.

The Weighing of Lithium Perchlorate.

When perfectly neutral, lithium perchlorate is not in the least deliquescent in air of ordinary humidity, but the presence of a very little acid suffices to make it so. After several days' exposure the pure salt is still apparently dry. Nevertheless, great care was taken not to expose the contents of the evaporating flask to the air. The ground stoppers of the flask were always kept closed, and although they were not quite as tight as those on the weighing bottles for the lithium chloride, they were evidently sufficient for the purpose.

In order that the apparent weight of lithium perchlorate might be corrected to a vacuum standard, the density was found by determining the weight of toluene displaced by a known quantity of salt. The toluene had been dried over sodium and then distilled. Its density at 25° referred to water at 4° was found to be 0.8617. Pure lithium perchlorate was fused in a quartz crucible in a current of dry air, broken into coarse pieces and transferred to an Ostwald pycnometer, modified for use with solids. Great care was taken to remove all air bubbles by shaking in a vacuum. The following table records the results:

DENSITY OF LITHIUM PERCHLORATE.

Weight of $LiClO_4$ in vacuum, grams.	Weight displaced toluene in vacuum.	Density of $LiClO_4$ 25°/4°.
5.2866	1.8757	2.4285
5.2866	1.8760	2.4283

The mean value is 2.428, and assuming the density of the weights as 8.3, a correction of 0.0003501 gram was added to every apparent gram of lithium perchlorate.

The weighing of the evaporating flask with its counterpoise proved to be rather troublesome. During the first few minutes on the balance, the flask lost somewhat in weight, frequently as much as 0.20 mg.; but eventually the weight became constant. Since both flasks showed this behavior it was not a serious matter, for constancy with respect to one another was all that was required. After waiting until constancy had been reached, the weight of the flask obtained after replacing it a second time upon the balance was usually within a few hundredths of a milligram of the first one. The initial irregularity may have been due to adsorbed moisture, but was more probably due to slight temperature changes, for with so large a vessel half a degree Centigrade would cause this difference. Hence the temperature of the balance case and the flasks should not change appreciably during the weighing; the more nearly this condition was realized, the more accurate was the result. A large pane of glass was placed between the observer and the balance to prevent the heat of the body from reaching it.

Impurities in the Fused Perchlorate.

There could have been only four possible impurities in the salt (provided that the lithium chloride and the perchloric acid and water were pure, and that the vessels were not attacked), namely, chloride, chlorate, hydroxide and water. The tests for these will be discussed in order.

After the flask had been weighed, its contents were dissolved in 0.1 liter of water, and the chloride present in 25 milliliters was determined in the nephelometer. The amount was always small—usually less than 0.002 per cent.—and the corresponding correction averaged about four-tenths of a milligram in 14.3 grams of perchlorate. The following table contains a statement of the amounts of chloride found in each of the final experiments, and a correction which was applied to the final weight of lithium perchlorate containing these impurities in order to allow for the oxygen lost. It is evident that for every 0.425 milligram of lithium chloride found, 0.64 gram of oxygen must have been lost, these quantities being in proportion to the combining weights. In the last determination, involving over 22 grams of perchlorate, the correction was so small as to be practically negligible; and in only one or two cases, in which the heating had probably been somewhat too rapid, did the total correction amount to any serious quantity.

Traces of chlorate were always likely to be present with the chloride, and since the quantity was very small, it was most conveniently estimated nephelometrically after reduction with a solution of pure sulphur dioxide. This gave the total chloride, the amount corresponding to the chlorate being obtained by subtracting that previously found as chloride. The correction for chlorate was usually entirely negligible; its amount was determined in four cases, analyses 1, 2, 7 and 11. Only in the last of these cases where the amount of lithium chloride found was unusually large did the necessary correction equal one-twentieth of a milligram; it was usually less than one-thirtieth. As a rule the more chloride present, the greater was the amount of chlorate, although the proportionality was not exact. Because one-twentieth of a milligram was only one part in 300,000 of the weight of perchlorate in the case of Experiment 11, and the amount present did not exceed this fraction in any of the other cases, the correction might have been entirely neglected without introducing appreciable error.

No. of experiment.	Weight of LiCl found. Milligram.	Correction applied to weight of $LiClO_4$. Milligram.
7	0.13	+0.20
8	0.50	+0.75
9	0.16	+0.24
10	0.21	+0.32
11	0.52	+0.78
12	0.06	+0.09

The formation of alkali was never observed, the solution of the perchlorate being always absolutely neutral to indicators. Even when the salt is *completely* decomposed into chloride, only a little oxide or hydroxide is formed, and in the specimens obtained in this work where only a trace of any kind of decomposition occurred, the amount of alkali must have been infinitesimal indeed.

Although it seemed probable that the salt dried under these conditions was perfectly anhydrous, the inference could only be verified by complete decomposition, as in the corresponding work of Richards and Forbes on silver nitrate. Lack of time has thus far prevented the completion of this final test, but a comparison of our work with the results of these authors indicates that the amount of water, if any, must be extremely small. They found certainly not over 0.001 per cent. in silver nitrate dried one hour at 210°, while the lithium perchlorate was heated to 300° for four or five hours in perfectly dry air. The correction for 0.001 per cent. of water in the perchlorate would raise the atomic weight of silver only 0.002.

Valuable information concerning the probably anhydrous nature of the salt, corroborating the above conclusions based on analogy, was actually obtained in four cases. During the progress of analysis 8 the lithium perchlorate was heated in the first place for four hours at 280°. Three hours more at about the same temperature caused a further loss of only 0.19 milligram, or 0.002 per cent. This loss, being much less than the weight [illegible] oxygen lost by the substance, may have been entirely due to the incipient decomposition. At any rate, even supposing the loss had been due to water, one might well infer that further heating could hardly expel more than 0.1 of a milligram additional. As will be seen, this inference was verified later. The ninth experiment was treated in dry air for six hours at 252°, a temperature at which the water would undoubtedly be expelled much less rapidly. Two and a half hours more at a temperature 30° higher caused the expulsion of about 0.2 milligram, and yet three hours more at the same temperature caused a further loss of but little more than 0.1 milligram. Thus only 0.003 pr cent. of the weight of the salt dried at 252° was lost by prolonged heating at 285°. Even this loss may have been due chiefly to oxygen, of which 0.24 milligram was shown to be lacking by the presence of 0.16 milligram of lithium chloride in the product.

In Experiments 11 and 12 higher temperatures were used. After having been dried for four and a half hours at 290–300°, the lithium perchlorate in this experiment weighed 17.84843 grams, and after further drying in a current of pure dry air for three hours at 300°, it weighed 17.84842, a loss of only 0.01 of a milligram. It seemed unlikely that further heating even at this high temperature would cause any further loss of weight. The last experiment, No. 12, was the most conclusive of all. The salt was first dried for five hours at 280° and was found to weigh 22.58271 grams. After three hours further heating at 280°, three hours more at 300°, and a few minutes at 310°, the specimen weighed 22.58275, a slight *gain*, but one not exceeding a possible error of weighing. Further heating for one hour at 300° caused an opposite change of only one-thirtieth of a milligram in this salt. The weight accepted as the true one was 22.58273, and one can hardly believe that this substance still retained an appreciable amount of water. These weighings demonstrated not only the probable absence of water, but also the striking stability of the salt.

The four impurities which might possibly have come from the pure materials employed have thus been discussed in detail. It remains to consider the impurities which might have come from the vessels used and from the gases in contact with the fused materials.

The lithium chloride (forming the starting point of the determination) was fused in a platinum boat. In most of the experiments this boat was weighed before and after the fusion, and was usually found to have lost but little. For example, in Experiment 7 the loss was 0.02 milligram, and in Experiment 8, 0.05 milligram and in Experiments 9 and 10, taken together, only 0.01 milligram. Thus in four experiments involving the fusion of over 18 grams of lithium chloride the total loss of weight was only 0.08 milligram, or 0.0004 per cent. of the weight of the lithium chloride. On the other hand, in the last experiment, No. 12, which was otherwise the best of all, the boat lost much more in weight, because in this case a new boat had been employed to accommodate the unusually large quantity of material. The loss was here 0.3 milligram. There was every reason to believe, because in other cases the platinum was not attacked, that this excessive loss, amounting to 0.003 per cent. of the lithium chloride, was due, at least in part, to iron volatilized from the boat during fusion at high temperature in hydrochloric acid. The boat had indeed been previously cleansed by treatment with ammonium chloride at high temperatures as usual, but apparently the cleansing had been insufficient. The mean weight of the boat was taken as the true one. Even the maximum error resulting from this choice amounts to only one part in 60,000 of the weight of lithium chloride, a quantity which seems often to represent the limit of accuracy in experimental work of this kind. On the whole, the evidence is that the boats were not sufficiently attacked to cause any important constant error in the series of results.

Turning now to the quartz flask, the only other receptacle used during the experiments, it was easy to prove that this was not appreciably attacked during the experiments. In three cases in which no regrinding of joints or alteration in tare weight had been necessary, the following successive tares of the evaporating flask were found: Experiment 8, 0.00106; Experiment 9, 0.00103; Experiment 10, 0.00104. This practically proves that the flasks were not appreciably attacked by the acid lithium perchlorate at 300°. It is of course possible that the flasks gained from the fused mass a weight of lithium equal to the weight of silica dissolved, but this is unlikely, especially because the flasks to-day, after all the determinations, still appear perfectly clear and transparent as they did at first.

Neither sodium chloride, silver chloride, nor silver nitrate were found in the previous investigations[1] to retain on fusion perceptible amounts of oxygen or nitrogen or argon, and, as the air and nitrogen passed over the lithium chloride and lithium perchlorate in the present experiments were both free from other gases, it is reasonable to infer that these salts also did not contain dissolved gas. The absence of hydrochloric acid from the lithium chloride which had been fused in the gas, and subsequently while fused heated in a current of pure nitrogen, was proved by complete neutrality of the dissolved product.

From these considerations it would appear that both the lithium chloride and lithium perchlorate were obtained in these experiments in a state of purity as great as is practicable in the present state of work of this kind, and therefore that the conclusions based upon the quantitative results are inferior to none.

[1] Richards and Wells, *Publ. Carnegie Inst. Washington*, 28, 55, 60 (1905). Richards and Forbes, *Ibid.*, 69, 55 (1907).

There follows a table containing the four preliminary results which were brought to a satisfactory conclusion. The third and sixth of this preliminary series were vitiated by known experimental errors, due to inexperience with the processes involved. No great accuracy is claimed for these results, but they serve to show that the process was one which was capable of exact work, and afforded the valuable training needed to carry out the six consecutive final experiments which followed. The lithium chloride used in these preliminary experiments was not perfectly pure, being of the same quality as that used in the preliminary experiments of the other series. In calculating the last two columns of the table below, values for the ratio LiCl : Ag were chosen which corresponded with the particular samples of slightly impure lithium chloride used in each case, namely, 0.39298 for Experiments 1 and 2, and 0 39304 for Experiments 4 and 5. Thus a large part of the error due to impurities in the lithium chloride was eliminated:

RATIO OF OXYGEN TO SILVER, O_4 : Ag.

Preliminary Series

No of experiment.	Sample of salt.	Weight fused LiCl. vacuum.	Weight fused $LiClO_4$. vacuum.	$\frac{4O}{LiCl}$.	$\frac{4O.}{Ag}$	Atomic wt. of Ag.
1	O	4 24171	10 04596	1.50983	0.59333	107.87
2	O	5 09073	12 77683	1.50982	0 59333	107.87
4	D	4.03587	10.12750	1.50957	0.59324	107.88
5	D	5.19638	13.04021	1.50948	0.59329	107.87
				1.50962	0.59330	107.872

Thus the atomic weight of silver is shown by these preliminary results to be not far from 107 872. It is interesting to note that if Stas's value for the relation of lithium chloride to silver had been used in making the computation of these results, the atomic weight of silver recorded in the last column would have been 107 70. This value is quite impossible in view of results obtained in other ways, and serves to emphasize the grave error which unquestionably existed in Stas's work on lithium chloride.

These preliminary experiments having furnished an adequate preparation for the execution of an exact series of experiments, six syntheses yielding the following results were made. The lithium chloride used in the determinations was preparation C already used in previous work involving the comparison with silver. The advantage of using similar material in the two sets of experiments has already been emphasized. Every precaution was taken, and, although we feel that with the experience gained in these experiments, a yet more consistent series might be obtained, especially if somewhat larger quantities of material were used; nevertheless, it is evident that this degree of accuracy will not be easy to exceed.

The following table explains itself. The weight of lithium perchlorate given was in each case obtained by adding to the actual weights (corrected to the vacuum standard) the corrections for chloride given in the last column of the table on page 44, together with the vanishingly small corrections for chlorate mentioned just afterwards. In calculating the values given in the last and next to the last column, the ratio of lithium chloride to silver is assumed to be 0.392997 : 1 as previously stated at the conclusion of Part I. No experiment was rejected.

THE RATIO OF OXYGEN TO SILVER. O_4 : Ag.

Final Series.

No. of experiment	Weight fused LiCl (vacuum).	Corrected weight fused $LiClO_4$ (vacuum).	$\frac{4O}{LiCl}$.	$\frac{4O}{Ag}$.	Atomic wt. of silver.
7	5.09744	12.79265	1.50962	0.593276	107.876
8	4.20534	10.55416	1.50970	0.593307	107.876
9	4.54205	11.39912	1.50769	0.593302	107.871
10	4.45070	11.17008	1.50974	0.593323	107.867
11	7.11167	17.84842	1.50974	0.593323	107.867
12	8.99846	22.58273	1.50962	0.593276	107.876
	Sum. = 34.40566	86.34716	Av. = 1.50968	0.593301	107.871

Thus, according to this series of results, silver is 107.871, if oxygen is taken as 16.000, and the ratio of lithium chloride to silver is taken as 0.392997 : 1. A variation of 4 in the sixth decimal place of this latter ratio would cause a change of only 0.001 in the atomic weight of silver. There seems to be no doubt that the ratio of lithium chloride to silver is not much more in error than this, and accordingly that the atomic weight of silver given by this series of results is free from error due to the work described in the first part of the present paper. The probable error of the final result, 107.871, according to the method of least three squares, is 0.003. The only possibility of serious uncertainty seems to lie in the possible retention of water by the fused lithium perchlorate. This would obviously tend to make the atomic weight of silver appear lower than it is. Accordingly we are disposed to believe that the value 107.871 represents the lower limit. The last analysis, made with the largest amount of material and showing the least decomposition, was probably the most satisfactory determination of all, and it will be noticed that in this case the value is somewhat higher than the average. If silver is 107.871, lithium becomes 6.939, essentially the same as if silver were 107.88. Chlorine is somewhat more affected by this difference in silver, sinking from 35.457 to 35.454.

Further determinations carried out as this last determination was, together with other experiments in which the possible presence of water remaining in the final substance should be sought in the manner used by Richards and Forbes in the case of silver nitrate, are needed to settle the third decimal place in the atomic weights of silver and chlorine beyond doubt, but the present investigation seems unquestionably to show that the atomic weights proposed by Stas, both for silver and for lithium, were much too high, and that the recent conclusion of many chemists that the value for silver is not far from 107.88 is entirely justified.

It is worthy of note that this investigation, taken together with that of Richards and Wells, gives values for chlorine, lithium and silver referred to oxygen which are independent of all other work. That these values should agree so closely with other results obtained in such widely different ways is very reassuring as to the degree of precision now within reach.

Summary.

This investigation consisted in a careful study of three ratios, namely that of lithium chloride to silver chloride, that of lithium chloride to silver, and that of lithium chloride to lithium perchlorate. By means of the last two ratios, O_4 : Ag was calculated, and new values were obtained in this entirely new way for the atomic weights of silver, lithium and chlorine. In the process of this work new methods of purifying lithium salts, better than any preceding, were devised. Lithium chloride was fused in such a way as to show perfect neutrality to the most sensitive indicators, and was weighed in a strictly anhydrous condition. The preparation of perchloric acid also was subjected to rigid scrutiny, and this substance was made in a state of unusual purity. The sharpness of the end-point in the method used for determining the relation between silver and chlorine was much increased by cooling the solution to 0°, in order to diminish the solubility of silver chloride. In other respects the methods of analysis developed in previous Harvard investigations were used in the determination of chlorine. A new precise method was devised for converting lithium chloride into lithium perchlorate, and its sources of error were carefully examined. 45.56877 grams of lithium chloride were found in seven experiments to yield 154.0602 grams of silver chloride on complete precipitation; and in another series of seven experiments partly independent from these 46.63197 grams of lithium chloride were found to need 118.65894 grams of silver for complete precipitation. In yet another series of six experiments, entirely independent, but using a similar preparation of lithium chloride, 34.40566 grams of this substance were converted into 86.34716 grams of lithium perchlorate. As an outcome of all these experiments, the atomic weight of lithium was found to be 6.939, and the atomic weight of silver 107.871, if oxygen is taken as 16.000.

THE SOLUBILITY OF SILVER CHLORIDE, BARIUM SULPHATE, AND CALCIUM SULPHATE AT HIGH TEMPERATURES.

BY ARTHUR C. MELCHER.

Received November 1, 1909.

Contents.

1. Outline of the investigation. 2. Previous investigations upon these substances. 3. Apparatus and method. 4. Preparation of the materials. 5. Conductance of solutions saturated with silver chloride and barium sulphate. 6. The solubility values for silver chloride and barium sulphate. 7. Conductance of calcium sulphate solutions of known concentration. 8. The specific conductance of solutions saturated with calcium sulphate. 9. The solubility values for calcium sulphate. 10. Discussion of the solubility relations of calcium sulphate. 11. Summary.

1. Outline of the Investigation.

The solubility of many difficultly soluble salts at room temperatures has already been determined by several investigators[1] by means of measurements of the electrical conductance of the saturated solutions. At the higher temperature of 100° Böttger,[2] working in this laboratory with the platinum-lined steel bomb used for conductivity measurements, determined the conductance of the saturated solutions of three silver salts.

The purpose of the present investigation was to apply this method to other salts at the high temperatures. The solubilities of silver chloride and barium sulphate, which are of great importance in analytical chemistry, were determined at 18, 50 and 100°. In addition, conductance measurements of saturated solutions of calcium sulphate were made at the temperatures 18, 50, 100, 156 and 218°, and the solubility and existence of its three forms, gypsum, soluble anhydrite, and ordinary anhydrite, were studied by this method. This substance was chosen for investigation partly because of the great importance of a knowledge of its solubility relations from the standpoint of geological and industrial chemical processes.

2. Previous Investigations upon These Substances.

Kohlrausch and Rose, Holleman, and Böttger[3] measured the conductance of saturated solutions of silver chloride, barium sulphate, and gypsum at temperatures between 2 and 42°. After subtracting the measured conductance of the water, they calculated the corresponding solubility by means of approximate values of the equivalent conductance at zero concentration. Two later articles of Kohlrausch give new values of the solubility, based upon more recent determinations of the equivalent conductances.

Goodwin[1] calculated the solubility of silver chloride at 25° from measurements of the potential difference of two silver electrodes, one of which was placed in a silver nitrate solution and the other in a potassium chloride solution saturated with silver chloride.

Böttger, as above stated, made preliminary experiments on the solubility of silver chloride at 100° in the platinum-lined bomb.

The solubility of gypsum between 0 and 100° has been determined by numerous investigators by evaporating a known volume of its saturated solution and weighing the residue. The literature relating thereto has been discussed by Hulett and Allen[2] in connection with their own careful determinations.

At higher temperatures Tilden and Shenstone[3] made rough measurements by heating an excess of solid salt with water in a silver-plated gun-metal tube, decanting while still hot through a platinum gauze partition into another part of the tube, cooling in the air, and analyzing the decanted solution. Boyer-Guillon[4] determined the solubility of calcium sulphate by heating a solution of it in a bronze autoclave for some hours at the temperature in question and then withdrawing portions through an asbestos filter.

3. Apparatus and Method.

The conductance measurements were made in a bomb such as is described by Noyes and Coolidge.[5] The electrode was of platinum-iridium, a cylinder dome-capped in shape, and polished so that none of the solid salt in suspension would adhere to it. The bomb carriage[6] was connected by means of gearing to an electric motor so that the bomb could be turned over and over continuously about twelve times per minute. The measurements from 18–156° were made in this way within an electrically heated bath of liquid pseudocumene. Those at 218° were made in a naphthalene-vapor bath, the bomb being rotated occasionally by hand.

The conductance capacity of the bomb was determined by measuring in it the conductances of 0.002 normal potassium and sodium chloride solutions at 18°, and was thus found to be 0.1224 and 0.1225.

It was proved that the conductance of a 0.01 normal potassium chloride solution in the bomb was not measurably changed by the addition of some solid silver chloride, showing that the presence of the solid in suspension would make no appreciable error in the conductance measurements.

The solubility determinations were made in the following manner, except in the cases noted in a later section: About one cubic centimeter of the moist well-washed salt was placed in the bomb and further washed by decantation. Water whose conductance had been determined in a glass cell was introduced into the bomb, and the bomb was closed. The bomb was next rotated at each successive temperature until the conductance was constant for fifteen minutes. The bomb was then carefully opened and the solution decanted off, a quantity of fresh water was added to the same salt, and the process was repeated until the conductances of the successive solutions at each temperature were practically identical.

Conductance measurements with water alone were made in the bomb under the same conditions, so as to determine the water correction. In these cases, the same method of treatment and the same time of heating were followed. The results are given in Table I:

Table I—Values of the Specific Conductance × 10^6 of Water.

4. Preparation of the Materials.

Two samples of silver chloride were prepared in a photographic darkroom illuminated only by red light. Sample I was prepared as follows: A solution, approximately 0.1 normal, of silver nitrate was heated to 100° in a water bath. A solution of 0.1 normal hydrochloric acid was dropped slowly into the hot silver nitrate solution with constant stirring. The silver chloride was washed by decantation, the chloride settling out very quickly. Sample II was prepared in the same way from silver nitrate and potassium chloride solutions. The washed chloride was, however, in this case further washed by shaking with a dilute ammonia solution in a bottle. The remaining chloride was treated with cold ammonia, 0.96, until about three-fourths of it had dissolved, and the solution was separated by decantation. This solution was heated slowly with vigorous stirring, and the precipitated chloride was washed by decantation. Both samples were kept under water in the dark.

Barium sulphate was prepared by dropping a 0 1 normal barium chloride solution into a hot 0.1 normal sulphuric acid solution which was constantly agitated by a revolving stirrer. The salt was washed by decantation and rotated for hours in hot water. The smaller particles were then washed away by decantation.

Calcium sulphate was prepared both in the form of gypsum and of anhydrite. A quantity of Kahlbaum's C. P. calcium sulphate was washed by long agitation with several portions of water. Conductivity water was then saturated with this salt at the temperature of its maximum solubility (35–40°), and the solution was then partially evaporated at a temperature below 60°, yielding the sample of gypsum. The anhydrite was obtained by dehydrating the salt so obtained by heating at 200° for twelve hours, when a constant weight had resulted.

The water used in the solubility determinations was prepared by redistilling ordinary distilled water to which alkaline permanganate solution was added, from a copper still with a tin condenser. This water was used directly in the work with calcium sulphate. For the solubility experiments with silver chloride and barium sulphate, this water was again redistilled from a special tin-lined still with a block-tin condenser. Only those portions from either distillation which had a specific conductance less than 0.8×10^{-6} were used in the investigation.

5. Conductance of Solutions Saturated with Silver Chloride and Barium Sulphate.

The specific conductances of the saturated solutions of silver chloride and barium sulphate are given in Table II. The column headings are for the most part self-explanatory. All the conductance values are expressed in reciprocal ohms and multiplied by 10^6. The specific conductance value given for the water employed are those measured in the glass cell at 18 or 25°:

TABLE II.—SPECIFIC CONDUCTANCE DATA FOR SATURATED SOLUTIONS OF SILVER CHLORIDE AND BARIUM SULPHATE.

			(3.99)	6.60	....	...	...	....	19.8[4]

[1] 18° in the experiments with AgCl, 25° in those with BaSO$_4$.

[2] The values at 18° were 3.01 and 2.94 in these two experiments.

[3] This increased to 24.6 in 45 minutes.

[4] This increased to 25.0 in 30 minutes.

The conductance of the saturated silver chloride solutions became constant in about twenty minutes. Preliminary experiments carried to the higher temperature 156° showed the impracticability of making any determinations above 100°. The large increase of conductance with the time in the case of barium sulphate at 156° is shown in the footnotes of the table. When, as in the third experiment, the solution was not heated above 100°, the final value at 25° is seen to be only slightly larger than the initial value; but when heated to 156°, as in the first two experiments, it was nearly doubled in less than an hour. The last row in the table shows directly the effect of heating to 156° the solution (represented by the row above) which had been previously heated to 100°.

6. The Solubility Values for Silver Chloride and Barium Sulphate.

From the specific conductances of the saturated solutions given in Table II, the conductance of the water was first subtracted, this being derived from Table I by multiplying the mean "bomb" values there given by the ratio to 0.50 of the specific conductance shown by the water in question when measured in the glass cell. As final values for barium sulphate were adopted the so-called initial values obtained in the last experiment (on July 29th) when the salt had been most fully leached out. As final values for silver chloride at 18 and 50° the mean of the initial values obtained in the last experiment with each sample (on Feb. 27th and March 3rd) were adopted. The value for silver chloride at 100° was corrected by determining the temperature coefficient of the contamination from the difference of the initial and final values at 18 and 50° and subtracting the proportionate value at 100°. The following specific conductances × 10^6 were thus derived:

TABLE III.—SPECIFIC CONDUCTANCE OF SATURATED SOLUTIONS OF SILVER CHLORIDE AND BARIUM SULPHATE.

Substance.	18°.	25°.	50°.	100°.
Silver chloride........	1.26	....	7.90	57.9
Barium sulphate........	2.30	3.00	6.45	14.0

By dividing the values given in Table III by the sum of the equivalent conductances of the separate ions, as given by Johnston,[1] the ion-concentrations in the saturated solutions were calculated. The results expressed in milli-equivalents per liter are given in Table IV:

TABLE IV.—ION CONCENTRATION IN THE SATURATED SOLUTIONS OF SILVER CHLORIDE AND BARIUM SULPHATE.

Substance.	18°	25°.	50°.	100°.
Silver chloride.............	0.0105	....	0.0363	0.146
Barium sulphate............	0.0187	0.0208	0.0281	0.0322

---

[1] THIS JOURNAL, 31, 1015 (1909). The values of Λ_0 which were employed are

	18°.	25°.	50°.	100°.
AgCl..................	119.8	...	217	395
$BaSO_4$..................	123	144	229	434

These values of the ion-concentration differ somewhat from those of the total concentration of the salt in the saturated solutions. The extent of the difference may be determined by estimating the degree of ionization in these very dilute saturated solutions by means of the ionization formula $(1 - \gamma) = K\,C^{0.5}$, which corresponds to the conductance formula employed by Kohlrausch. The constant K for barium sulphate was assumed to be the same as for calcium and magnesium sulphates, and was derived for these salts from the ionization data at 2 millinormal given in Table VIII. That for silver chloride was assumed to be the same as for silver nitrate, the ionization value for the latter at 2 millinormal given by Noyes and Melcher being employed. By dividing the ion concentration given in Table IV by the ionization values so determined, the total concentrations (in milli-equivalents per liter) in the saturated solutions, given in Table V, were obtained:

TABLE V.—SOLUBILITY OF SILVER CHLORIDE AND BARIUM SULPHATE.

Substance.	18°.	25°.	50°.	100°.
Silver chloride	0.0105	...	0.0365	0.147
Barium sulphate	0.0190	0.0212	0.0288	0.0334

These results at 18° may be compared with those previously found by Kohlrausch and Böttger. Kohlrausch's[1] values are 0.0094 for silver chloride and 0.0197 for precipitated barium sulphate. It seems probable that the lower values are more accurate in each case. Böttger's[2] values for silver chloride at 19.95° were 3 per cent. larger than Kohlrausch's. His value[3] for the specific conductance of that salt at 100° is 56.7×10^{-6}, which is nearly identical with that given in Table III. When divided with the same Λ_0 value as that used by me, it gives a solubility of 0.0143 milli-equivalents per liter. At the time of his measurements the agitation of the bomb was done by hand instead of by a mechanical rotating arrangement, which made the securing of saturation at exactly 100° more difficult.

From the solubilities of these salts at 18, 50, and 100°, the heat absorbed by the solution of one formula weight of the salt was calculated by solving the two simultaneous equations:

$$\log_e \frac{S_{50}}{S_{18}} = \frac{L_0}{2R}\left(\frac{1}{291} - \frac{1}{323}\right) + \frac{\alpha}{2R}\log_e \frac{323}{291}.$$

$$\log_e \frac{S_{100}}{S_{50}} = \frac{L_0}{2R}\left(\frac{1}{323} - \frac{1}{373}\right) + \frac{\alpha}{2R}\log_e \frac{373}{323}.$$

These are the forms obtained by integrating the fundamental thermodynamic equation

---

[2] *Ibid.*, 46, 602 (1903).

[3] *Ibid.*, 56, 93 (1906).

$$d \log S = \frac{L}{2RT^2}\, dT$$

for the case that $L = L_0 + \alpha T$, and by substituting the appropriate values of T.

By these calculations the value in calories of L, the heat absorbed by the solution of one formula weight of the salt at the absolute temperature T was found to be:

$$L = 34200 - 60.5\ T \text{ for silver chloride;}$$

and $$L = 30800 - 85.2\ T \text{ for barium sulphate.}$$

For $T = 273 + 18$, this expression yields:

$$L = 16600 \text{ cal. for AgCl; and } L = 6000 \text{ cal. for } BaSO_4.$$

The heat evolved by the precipitation of these salts when produced by the metathesis of silver nitrate and hydrochloric acid or of soluble barium salts and sodium sulphate was found by Thomsen to be 15800 calories for silver chloride[1] and to be 4970 calories for barium sulphate.[2] Considering the inaccuracy of the very small solubility values at 18°, the agreement is perhaps as close as could have been expected.

7. Conductance of Calcium Sulphate Solutions of Known Concentration.

A stock solution of calcium sulphate was made by dissolving some of the salt in conductivity water. The concentration was determined by precipitating the calcium as oxalate, filtering, and washing the precipitated calcium oxalate, and then titrating it in hot acid solution with potassium permanganate solution, which had been standardized against sodium oxalate ("nach Sörensen") It contained 23.50 milli-equivalents per liter. More dilute solutions were made by weighing out some of the stock solution and making up to a known volume.

The conductivity data are given in Table VI. The first two columns are self-explanatory. The third column gives the concentration at the temperature of the measurement expressed in milli-equivalents per liter. The fourth column gives the specific conductance of the solution corrected for all instrumental errors. The fifth column gives the calculated equivalent conductance after correcting for the conductance of the water.

Using as a means of interpolation the formula $C(\Lambda_0 - \Lambda) = K(C\Lambda)^{1.5}$, the values at round concentrations given in Table VII were obtained. The values at zero concentration are the sums of those derived for the calcium and sulphate ions by Johnston[3] from measurements with other substances.

[3] THIS JOURNAL, 31, 1015 (1909)

TABLE VI CONDUCTANCE OF CALCIUM SULPHATE SOLUTIONS

Date. 1908	Concentration at 4°.	Temperature t°	Concentration at t°.	Specific conductance x 10^6.	Equivalent conductance.
May 11. .	1.976[1]	18	1.973	193.7	97.8
		50	1.952	346.7	176.7
		100	1.894	568.0	299.0
		156	1.799	637.0	352.0
May 5	3.951	18	3.946	354.7	89.7
		50	3.904	629.0	160.8
		100	3.788	990.0	261.0
		156	3.598	1044.0	289.0
		18	3.946	355.1	89.8
May 6	7.988	18	7.978	645.0	80.7
		50	7.894	1127.0	142.7
		100	7.658	1706.0	222.0
May 7	23.53	18	23.50	1558.0	66.2
		50	23.25	2640.0	113.5
		100	22.55	3800.0	168.5

The value of the exponent n in the expression $C(\Lambda_0 - \Lambda) = K(C\Lambda)^n$ that best corresponds to these results at 18° was found to be 1.50. It is therefore of about the same magnitude as in the case of the uni-univalent and uni-bivalent salts previously studied. In the case of the values of Hulett, which extend over a wider range of concentration, the double curvature[2] due to a change in the value of the exponent n was clearly evident.

TABLE VII.—EQUIVALENT CONDUCTANCE OF CALCIUM SULPHATE AT ROUND CONCENTRATIONS.

Concentration	18°.	50°.	100°.	156°.
0	119.0	223.0	425.0	682
2.0	97.7	176.0	295.0	341
4.0	89.6	160.0	258.0	280
8.0	80.7	142.4	220.5	
10.0	77.7	136.5	209.0	
20.0	68.5	118.0	174.0	

Plotting the data of Hulett[3] in the same way, so as to get the values of the equivalent conductance for corresponding concentrations, the following results were obtained. The two series are seen to be in excellent agreement:

Concentration.	Melcher.	Hulett.
2.00	97.7	97.4
4.00	89.6	89.6
8.00	80.7	80.7
10.00	77.7	77.7
20.00	68.5	68.6

---

[1] This soluti[illegible] was heated to 218°, but even this dilute solution was so supersaturated th[illegible] it began to precipitate out before the temperature was reached.

[2] [illegible] value [illegible] AL, 31, 74[illegible]

From the equivalent conductance values given in Table VII, the ratio $100\ \Lambda/\Lambda_0$ corresponding to the percentage ionization of the calcium sulphate was calculated. The resulting values are given in Table VIII beside those previously obtained[1] for magnesium sulphate. The degree of ionization of calcium sulphate is seen to be substantially the same as that of magnesium sulphate at 18°, but distinctly less at 100 and 156°.

8. The Specific Conductance of Solutions Saturated with Calcium Sulphate.

The data obtained with the saturated solutions of calcium sulphate are contained in Table IX. The first column contains the number of the experiment, each series of measurements made with a new charging of the bomb with fresh water being indicated by a letter attached to the preceding number and each series where both salt and water were renewed being given a separate number. The second column contains the date. The third shows the form of solid salt which had been originally introduced, G representing gypsum and A anhydrite. The fourth column contains the (corrected) temperature. The fifth and sixth columns show the values of the specific conductance in reciprocal ohms multiplied by 10^6, those under "first value" being measured as soon as the temperature of the bath had presumably been attained and those under "last value" being measured after the interval of time in minutes shown in the seventh column. The last column shows the change in specific conductance per minute which was still taking place during the last ten minutes of that interval; where dots are inserted, the reading was constant. Whether saturation was approached from a higher or lower temperature is indicated by the temperature given in the row next above, except that in passing from 218 to 156° the bomb was always cooled *below* the latter temperature before introducing it into the bath.

In deriving final values of the conductance and solubility at the different temperatures it is necessary to take into consideration the character of the solid phase in contact with the solution, for this may be present in different forms under the different conditions. To make clear the relations here involved, the results of two of the most complete experiments (No. 5*a* and the latter part of No 4*a*) are represented graphically in Figure 1, in which the abscissae denote somewhat arbitrary intervals of time. The upper graph shows the behavior of a solution made by introducing gypsum as the solid substance. This is the solid phase still present in the first measurement at 100°, and the figure shows that heating to 110° for a short time does not transform it, since on returning to 100° the conductance has the same value as before. After heating to 135°, however, the conductance is seen to return to an appreciably lower value at 100°, and this same value is again obtained after heating to 156°. Considering now the lower graph, which represents the behavior of a solution made by adding anhydrite to hot water (above 70°), it will be seen that upon coming down from 218 to 156° and later to 100° much lower values of the conductance are obtained at both temperatures

---

[1] The bomb was rotated in the neighborhood of these temperatures until the conductance was practically constant. The values of the latter (enclosed within parenthesis) are very rough ones.

(whether approached from above or a little below) than in the other experiment where gypsum was the added substance. These facts make

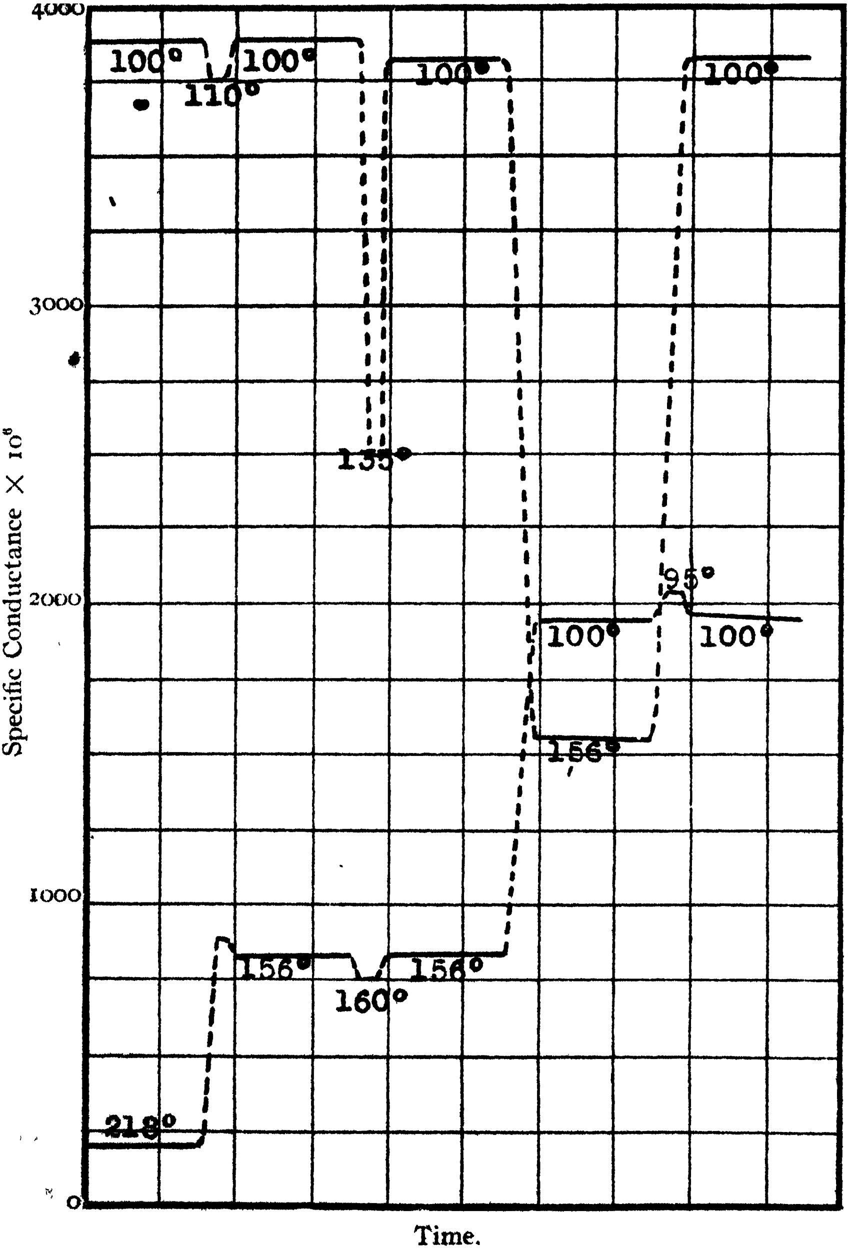

Fig. 1.

it clear that there are in the different cases three different solid phases involved. That corresponding to the highest conductance value at 100° is doubtless gypsum, and that corresponding to the lowest conductance values at 100° and at 156° is doubtless ordinary anhydrite. The intermediate value at 100° and the higher one at 156° must correspond to a third solid phase. This might be either another hydrate or another form of the anhydrous salt. Its solubility relations, namely, the temperature at which its solubility curve intersects that of gypsum and the constancy (at 100 and 156°) of the ratio of its solubility to that of the anhydrite, prove, as will be seen below, that it is the latter and that it is undoubtedly identical with the "soluble anhydrite" of van't Hoff.[1]

Table X contains final values of the conductance of the solutions saturated with these three different forms:[2]

TABLE X.—SPECIFIC CONDUCTANCE × 10^6 OF THE SATURATED SOLUTIONS OF CALCIUM SULPHATE.

9. The Solubility Values for Calcium Sulphate.

To determine the corresponding solubility values, the concentrations of calcium sulphate, which would give at the various temperatures the specific conductances recorded in Table X, were calculated as follows: With the data given in Table V for solutions of known concentration plots of $1/\Lambda$ against $(C\Lambda)^{0.5}$ were made, Λ representing as usual the equivalent conductance, C the equivalent concentration, and $C\Lambda$ therefore the specific conductance × 10^8. From these plots the values of Λ corresponding to the values of the specific conductance of the saturated solution were taken off, and by dividing the latter by the former values, the concentrations of the saturated solutions were obtained. The result at 218°, however, is only an estimate obtained by dividing the fairly accurate value of the ion concentration in the saturated solution given below in Table XIII, by the degree of ionization, this latter being estimated to be about 30 per cent. through a consideration of the ionization values at 218° obtained for magnesium sulphate by Noyes and Melcher.[3]

---

[1] *Z. phys. Chem.*, 45, 273 (1903).

[2] For the solutions saturated with gypsum at the various temperatures these values are means of all the "last values." For the solutions saturated with anhydrite the mean of the last four values at 156 and 218° given in the table was taken, and at 100° for both forms of anhydrite the mean of all the constant values was taken. For the soluble anhydrite at 156° the mean of the last two measurements was taken.

[3] By plotting their values of the ionization γ against $(C\gamma)^{0.5}$ and extrapolating, it is found that $\gamma = 0.36$ for $C\gamma = 0.2$ millinormal; and we have assumed that for calcium sulphate the value is 15 per cent. less than this, upon the basis of the results at 156°.

This solubility value at 218° is almost certainly correct within 0.1 milli-equivalent.

Table XI contains the solubility values expressed in milli-equivalents per liter:

TABLE XI.—SOLUBILITY VALUES FOR CALCIUM SULPHATE.

Form.	18°.	50°.	100°.	156°.	218°.
Gypsum	29.5	30.0	23.3	...	...
Soluble anhydrite	. .	....	22.8	6.4	...
Anhydrite	....	....	9.2	2.7	0.7

The results obtained by other investigators or interpolated from their values are placed beside mine in Table XII:

TABLE XII.—COMPARISON OF THE SOLUBILITY VALUES WITH THOSE OBTAINED BY OTHER INVESTIGATORS.

Solid phase	Temperature.	Melcher.	Hulett and Allen.[1]	Boyer-Guillon.[2]	Tilden and Shenstone.[3]
Gypsum	18°	29.5	29.6	...	...
"	50°	30.0	30.1	...	...
"	100°	23.3	23.8	24.2	...
Anhydrite	200°	0.9	...	....	...
Soluble anhydrite	200°	. .	. .	2.3	3.7

It will be seen that the new values agree almost perfectly with those obtained by Hulett and Allen by an entirely different method. They also agree well with the results of Boyer-Guillon at 100 and 156°. His much higher value at 200° seems clearly to have been due to the fact that the solid phase in contact with the solution was still soluble anhydrite. This conclusion is confirmed by the fact that the ratio (2.3 : 0.9 = 2.5) of the solubility of the two anhydrites at 200° is nearly the same as that (2.4) at 156°—a relationship discussed more fully below. His results therefore supplement those here presented in an important way by showing the solubility of that phase at higher temperatures than those at which it was determined in these experiments. The values of Tilden and Shenstone are probably too high, owing to errors involved in their method.

It seems desirable to give also the values of the equivalent concentrations of the ions in the saturated solutions. These are given in Table XIII. They were obtained by dividing the measured values of the specific conductance given in Table X by the values of $\Lambda_{Ca} + \Lambda_{SO_4}$ (at zero concentration) as computed by Johnston:[4]

---

[1] THIS JOURNAL, 24, 474 (1902).

[2] *Ann. Conservatoire Arts et Metiers* [3], 2, 209 (1900).

[3] *Trans. Roy. Soc.* (*London*), 175*A*, 31 (1884).

[4] THIS JOURNAL, 31, 1015 (1909). The values of $\Lambda_{Ca} + \Lambda_{SO_4}$ employed are:

18°.	50°.	100°.	156°.	218°.
119	223	4.25	68.2	1060

The value at 218°, not being given by Johnston, was assumed to be somewhat (2 per cent.) less (as at 156°) than that previously computed for magnesium sulphate by Noyes and Melcher.

TABLE XIII.—EQUIVALENT CONCENTRATION OF IONIZED CALCIUM SULPHATE IN THE SATURATED SOLUTIONS.

Form.	18°.	50°.	100°.	156°.	218°.
Gypsum	15.69	14.47	9.13	. . .	. . . .
Soluble anhydrite			9.00	2.29	. . . .
Anhydrite			4.62	1.22	0.20

A comparison of these values with those given in Table XI shows that the ionization in the solution saturated at 100° with gypsum is 39 per cent. and that that in the solution saturated at 156° with anhydrite is 45 per cent.

10. Discussion of the Solubility Relations of Calcium Sulphate.

In order to make clearer the solubility relations of calcium sulphate, the values given in Table XI are represented graphically in Fig. 2. The curve given for gypsum has been completed with the aid of the data of Hulett and Allen, and that for soluble anhydrite with the aid of those of Boyer-Guillon. An additional point at 60° upon the anhydrite curve has been furnished by van't Hoff's determination[1] of the transition temperature for gypsum and anhydrite.

Attention may be called to the following facts shown by a consideration of the diagram and the values of Table XI:

Anhydrite is the stable form at temperatures above 60°. Its solubility decreases with great rapidity with rising temperature, having at 218° a value only one-fortieth as great as that of gypsum at 18°.

The solubility curve for soluble anhydrite cuts that for gypsum at a point corresponding to a temperature of about 97°. The transition temperature of these two forms was estimated by van't Hoff[2] from vapor-pressure measurements to be 93°, thus a few degrees lower. The agreement is, however, as close as could be expected.

The ratio of the solubility of soluble anhydrite to that of ordinary anhydrite is almost the same at 100 and at 156°, namely 2.48 at 100° and 2.37 at 156°. This fact is significant in showing that the former solid substance is, as assumed, another form of anhydrous calcium sulphate and not a hydrate, for it follows from the thermodynamic equation $d \log \frac{S_{II}}{S_{I}} = \frac{Q}{RT^2}\, dT$, that, when S_{II}/S_{I}, the ratio of the solubilities of the two forms is constant, the heat of transition Q is zero. While this would be highly improbable for the transition of an anhydrous into a hydrated salt, it is to be expected that the value of the heat of transition of two solid anhydrous substances of the same chemical composition would be very small.

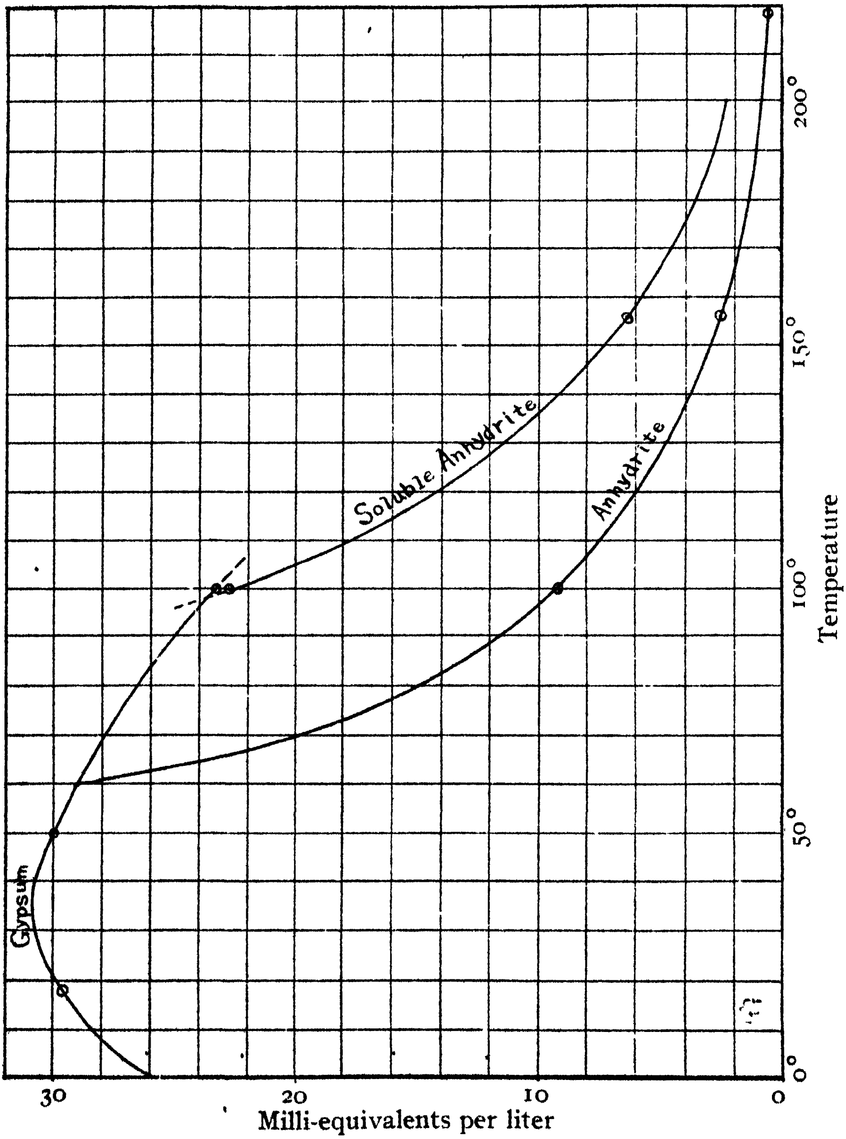

Fig. 2.

11. Summary.

In this article have been presented the results obtained by measuring in a platinum-lined steel bomb provided with a mechanism for rotating it within a liquid bath the conductance of solutions saturated separately with silver chloride and barium sulphate at 18, 50, and 100°, and with calcium sulphate at these temperatures, and also at 156 and 218°. The corresponding solubilities were calculated by dividing the values of the specific conductance so obtained by the appropriate values of the equivalent conductance, which last were derived in the case of the first two salts from the values for the separate ions at zero concentration, and in the case of the calcium sulphate from measurements (also presented above) of the conductance of solutions of it of known concentration. The final solubility values will be found in Tables V and XI, on pages 55 and 63. The heats of solution of silver chloride and barium sulphate were also calculated from these data.

In the case of calcium sulphate, the investigation included the study of the solubility relations of the three forms: gypsum, soluble anhydrite, and ordinary anhydrite. These relations are represented graphically in Fig. 2 on page 65. The transition temperature for the metastable system gypsum, soluble anhydrite, solution, was found, from the point of intersection of the solubility curves, to be about 97°. The solubility of the ordinary anhydrite was shown to decrease enormously with rising temperature, namely from 29.0 milli-equivalents per liter at 60°, where, according to van't Hoff, it is in stable equilibrium with gypsum, to 0.7 milli-equivalents per liter at 218°.

The ion concentrations in the saturated solutions of calcium sulphate have also been calculated and presented in Table XIII, on page 64.

The ionization relations of calcium sulphate have been compared with those for magnesium sulphate previously investigated in this laboratory by Noyes and Melcher. At 18° the degrees of ionization of the two salts are nearly identical; but at 100 and 156° the ionization of the calcium salt is a few per cent. less than that of the magnesium salt at corresponding concentrations.

This investigation has been carried out under the direction of Professor A. A. Noyes with the aid of a grant made to him by the Carnegie Institution of Washington. It is desired to express here grateful acknowledgment of this financial aid, by which this research has been made possible.

BOSTON, October. 1909.

THE PREPARATION OF PERCHLORIC ACID FROM SODIUM PERCHLORATE.[1]

BY FRANK C. MATHERS.

Received October 11, 1909.

Most of the methods for the preparation of perchloric acid depend upon the distillation under reduced pressure of a mixture of a perchlorate and sulphuric acid or of a crude perchloric acid that has been prepared by the decomposition of aqueous chloric acid by heat, by the action of sulphuric acid upon barium perchlorate, or by the action of hydrofluosilicic acid upon potassium perchlorate.

---

[1] NOTE.—This investigation was the result of a search for a cheap and convenient method for the preparation of perchloric acid, to be used in making perchlorate baths for the electroplating and refining of metals as described in the United States Patent, No. 931,944, issued to the author.

Kreider[1] has described a method which avoids this troublesome distillation under reduced pressure, which is easy of manipulation and which gives a very pure perchloric acid. His method is based upon the reaction expressed by this equation:

$$NaClO_4 + \text{conc. } HCl\ (+\ \text{excess conc. } HCl) = NaCl + HClO_4.$$

Solid dry sodium perchlorate is treated with an excess of concentrated hydrochloric acid. The mixture is then filtered and the residue of sodium chloride which is almost insoluble in the excess of hydrochloric acid is washed with concentrated hydrochloric acid. The filtrate is a mixture of perchloric acid, hydrochloric acid and small amounts of the sodium salts of these acids due to the slight solubility of the sodium chloride in the hydrochloric acid solution. By heating this filtrate until white fumes of perchloric acid are evolved, the hydrochloric acid is volatilized and the perchloric acid remains behind. The boiling points of the hydrochloric acid and the perchloric acid with 2 molecules of water (119 and 203° respectively) are so far apart that a very satisfactory separation is obtained.

The object of this research was to determine the best conditions and the proper quantities of reagents to use in order to obtain the best results from this process of Kreider, since the original article only gave a qualitative description of the method.

Twenty grams of sodium perchlorate (weighed to 1 mg.) was placed in a 100 cc. beaker and treated with the concentrated hydrochloric acid. The contents of the beaker were filtered upon a Gooch crucible and the residue of sodium chloride washed with ten 1 cc. portions of concentrated hydrochloric acid. The filtrate, which contained the aqueous perchloric acid and the excess of hydrochloric acid together with small amounts of the sodium salts of these acids, was evaporated upon a hot plate to volatilize the hydrochloric acid. The residue which did not volatilize below a temperature of 150° consisted of aqueous perchloric acid whose purity and yield depended upon the conditions of the experiment. These samples of perchloric acid were analyzed to determine the free perchloric acid, the sodium perchlorate and the hydrochloric acid. The residues of sodium chloride that were obtained by the first filtration upon the Gooch crucibles, were analyzed to determine the sodium perchlorate.

Methods of Analysis.—Free acids were determined by titration using methyl orange as indicator. The end point with perchloric acid was decisive and satisfactory. Volhard's method was used for the volumetric determination of the chlorides. The perchlorates in the free perchloric acid were determined by evaporating a measured portion to dryness in a platinum dish. The dish was then heated to near redness until the perchlorates were decomposed to chlorides. The end of this decomposition was easily detected since the perchlorates were easily fusible and the chlorides were infusible at this temperature. The total residue which consisted essentially of sodium chloride was calculated to sodium perchlorate. Of course this method would only correct results with samples containing perchloric acid, sodium perchlorate and easily volatile substances such as hydrochloric acid. The estimation of perchlorates in the presence of chlorides depends upon the determination of the difference between the chlorine in a sample that has been treated to decompose the perchlorates into chlorides and in an untreated sample. This decomposition can be accomplished very easily by the method of Dittrich and Hollenback.[1] The perchlorate is fused for several hours with sodium nitrite. After cooling, the fused mass is dissolved in water and the chlorine is determined by the method of Volhard. Porcelain dishes are attacked by the fused sodium nitrite so platinum vessels must be used. The sodium nitrite that was used in this research contained chlorine so a blank was determined and the proper correction was applied to each analysis. This method gave uniformly accurate results and was satisfactory in every way.

[1] Kreider, *Am. J. Sci.* [3], 49, 443; *Z. anorg. Chem.*, 9, 343. Treadwell and Hall, "Quantitative Chemistry," Vol. 2, page 47 (1904).

Materials Used.—A commercial preparation of sodium perchlorate was used. Its composition was: NaCl, 1.76, 1.86; $NaClO_4$, 95.38, 95.77 per cent.; $NaClO_3$, trace.

Commercial barium perchlorate was used. The material was "caked" in the bottle and an average sample for analysis was difficult to obtain. An analysis showed 53.5 per cent. of ClO_4. The C. P. hydrochloric acid which was used showed a specific gravity (spindle) of 1.16 at 24°. The commercial acid which was used in one experiment had a specific gravity of 1.14 at 24°, and each cc. contained 0.00097 gram of non-volatile matter.

TABLE I.—EFFECT OF WATER

The sodium perchlorate (20 grams) was dissolved in 7 cc. of water at 105° and then 20 cc. concentrated hydrochloric acid was added. For comparison the results without water are included in this table.

Grams water added. cc.	$HClO_4$ in the filtrate in terms of $NaClO_4$.		$NaClO_4$ in filtrate. Grams.	Total ClO_4 in filtrate. In terms of $NaClO_4$.		$NaClO_4$ in NaCl residue. Gram.
	Grams.	Per cent.		Grams.	Per cent.	
7.0	15.48	81.6	2.63	18.11	94.7	0.2
0.0	16.97	88.4	1.65	18.62	97.4	0.46

---

[1] Dittrich and Hollenback, *Ber.*, 38, 751 (1905).

This data shows that water should not be added.

TABLE II.—EFFECT OF THE QUANTITY OF HYDROCHLORIC ACID.

Cc. of HCl.	$HClO_4$ in the filtrate In terms of $NaClO_4$		$NaClO_4$ in filtrate.	Total ClO_4 in filtrate. In terms of $NaClO_4$.		$NaClO_4$ in NaCl residue.
	Grams.	Per cent.	Grams.	Grams.	Per cent.	Grams.
10	13.65	71.4	1.91	15.56	81.4	2.72
15	15.4	80.5	1.61	17.05	89.2	1.46
20	16.97	88.4	1.65	18.62	97.4	0.46
25	18.13	94.8	0.84	18.97	99.2	0.2
30	18.35	96.0	0.79	19.14	100.1	0.18
50	18.65	97.6	0.63	19.28	100.8	0.34

This table shows that 25 to 30 cc of hydrochloric acid should be used for each 20 grams of sodium perchlorate.

TABLE III.—TO FIND THE TEMPERATURE NEEDED TO EXPEL THE HYDROCHLORIC ACID FROM THE FILTRATE.

Temperature.	Cl in the filtrate. In terms of $NaClO_4$. Grams.
120°	2.006
130°	0.06
135°	0.0
145°	White fumes of $HClO_4$.

The filtrates containing the perchloric and hydrochloric acids were heated upon a hot plate. The sides of the beaker should be brought to the temperature of the experiment since, otherwise, the drops of the liquid which condense upon the upper part of the beaker retain hydrochloric acid. When the temperature of the entire beaker was brought to 135° there was not enough hydrochloric acid remaining to give an opalescence with silver nitrate. All of the hydrochloric acid could probably have been removed by maintaining the temperature somewhat below 135° for a period of time but this experiment was not tried. This table shows that all of the hydrochloric acid is volatilized at a temperature of 135°.

TABLE IV.—LOSS OF PERCHLORIC ACID DURING THE VOLATILIZATION OF THE HYDROCHLORIC ACID.

Volume of aqueous $HClO_4$ used.	Cc. of substances added.		Grams. of $HClO_4$ present.	$HClO_4$ lost.	
	H_2O.	HCl (conc.).		Gram.	Per cent.
40	0	..	6.97	0.09	0.13
40	50		6.97	0.14	0.20
40		90	6.97	0.19	0.27

The solutions were heated upon the hot plate until the temperature reached 135°. Any loss as small as that shown in this table can be neglected in a method of preparation.

TABLE V.—AMOUNT OF WASHING NEEDED TO REMOVE THE PERCHLORIC ACID FROM THE SODIUM CHLORIDE RESIDUES.

The residue was first drained by suction. It was then washed with 5 1 cc.-portions of concentrated hydrochloric acid, again drained by suction, then washed with a second five 1 cc.-portions of acid, etc. Each five 1 cc.-portions were saved separately and analyzed.

Conc. HCl used in washing	$HClO_4$ washed from the residue of NaCl. Grams.
First 5 1 cc.-portions	large amounts.
Second 5 1 cc.-portions	1.65
Third 5 1 cc.-portions	0.19
Fourth 5 1 cc.-portions	0.08

After washing with twenty portions of acid, 0.06 gram of sodium perchlorate still remained in the residue. This table shows that ten 1 cc.-portions of concentrated hydrochloric acid is the most economical amount to use in washing the residue from 20 grams of sodium perchlorate and 25 cc. of concentrated hydrochloric acid.

In one experiment 20 grams of barium perchlorate were treated with 60 cc. of hydrochloric acid. The precipitate of barium chloride was very bulky and voluminous, entirely filling an ordinary Gooch crucible. The 60 cc. of hydrochloric acid just made the residue liquid enough so that it could be poured upon the filter. The yield of perchloric acid was 80.9 per cent. of theory. Washing with ten 1 cc.-portions of hydrochloric acid failed to wash the perchloric acid out of such a bulky residue. Another experiment showed that "commercial" hydrochloric acid did not give as good results as the "C. P." acid. This was no doubt due to the lower concentration of the "commercial" acid. The yield of perchloric acid was 88.7 per cent. as compared to 96.0 per cent. for the "C. P." acid. Potassium perchlorate cannot be used.

Summary.

These experiments were made to determine the best conditions for the preparation of perchloric acid by the action of concentrated hydrochloric acid upon sodium perchlorate.

The sodium chloride is insoluble in the excess of concentrated hydrochloric acid and can be separated from the perchloric and hydrochloric acids by filtering upon an asbestos filter and by washing with concentrated hydrochloric acid. By heating the filtrate, the hydrochloric acid can be volatilized away from the perchloric acid. The best conditions are: Use 25 to 30 cc. of concentrated hydrochloric acid for each 20 grams of sodium perchlorate. Do not add any water to the substances. Filter out the sodium chloride residue and wash with ten 1 cc. portions of concentrated hydrochloric acid. Heat the filtrate and washings to 135° to volatilize the hydrochloric acid. The yield of perchloric acid is about 95 per cent. of the theoretical. Only about 1 per cent. of the sodium perchlorate is lost in the sodium chloride residues. The other 4 per cent. is in the perchloric acid as sodium perchlorate. The perchloric acid is free from chlorides. The process does not work with potassium perchlorate and is unsatisfactory with barium perchlorate.

UNIVERSITY OF INDIANA, BLOOMINGTON.

ORGANIZATION OF INDUSTRIAL RESEARCH.[1]

BY WILLIS R. WHITNEY.

Received November 6, 1909.

The intimate connection between the purely scientific research of a people and its advance in the art of good living cannot be too frequently discussed. The organization of industrial research involves arranging and maintaining a body of involute parts as an operative whole of highest efficiency. It is never perfectly accomplished, and the fact that improvement can always be made is an incentive for its discussion.

A recent copy of *Life* has this to say, which, without straining, bears directly upon industrial research:

"This is the most interesting country in the world. The game here is the biggest that is being anywhere played. The problems of humanity that are being worked out here are the greatest problems under consideration, and the prospect of solving them is better than it is anywhere else."

Lord Bacon said: "The real and legitimate goal of the sciences is the endowment of human life with new invention and riches." He, in turn, cited King Solomon, who said, "it is the glory of God to conceal a thing, but the glory of a king to search it out."

Bacon distinguishes three degrees of ambition:

First, that of men anxious to enlarge *their own* power *in* their own country. This is "vulgar and degenerate."

Second, that of men who strive to enlarge the power and empire of their *country* over mankind. This is "more dignified, but not less covetous."

Third, that of those who strive to enlarge the power and empire of *mankind* in general over the *universe*. Evidently this is the best, and is the real ambition, whether recognized or not by himself, of any good experimenter.

For purposes of systematic analysis, the subject, "Organization of Industrial Research," may be divided into two parts:

Part one, the personal or mental organization, with its requirements, etc.

Part two, the objective or material organization.

For brevity, these may be called the mind and the matter organizations.

The former, or personal, I will subdivide into such parts as:

Its training and characteristics.

Division of its labors.

Its records, etc.

The objective or matter organization, I divide into:

---

[1] An address delivered at the Twentieth Anniversary of Clark University, Sept. 17, 1909.

The fields for material research.

The laboratory equipment and systems of its material co-operation.

Naturally, the personal comes first, relatively and chronologically, and the mental precedes the material. The personal factor is *everything* in industrial research. Strangely enough, it is everywhere and always dominant, while every other factor is sometimes recessive. In an organization "A" cannot work well with "B" because one is too slow, too fast, to egotistical, too jealous, too narrow, etc. Nowhere else do the personal traits protrude so much as in concerted research And so I hold that above all, as an industrial experimenter, I should like as broad a *human* training as possible, before any other specific one This probably means little more than acquirement of a *demonstrated* desire to play fair, and it may be no more applicable to this field than to others.

To one always in close touch with research, it seems as though there is an immutable law of nature which may be stated as follows: (It is an application of the principle of reversible reactions so as to include the reactions of the mind.)

The equilibrium between mental and material conception is so sensitive that anything which, to the fair mind, seems possible, is to the trained persistence permissible. If this should be proven not strictly true, it would still be a good working hypothesis for a research organization.

This theory requires, then, a certain characteristic in the generally successful research operator. This is recognized in *optimistic activity* and, to my mind, should be placed first among the requisites It is placed above *knowledge*, because, without it, little that is new will ever be done except by accident. With active optimism, even in absence of more than average knowledge, useful discoveries are almost sure to be made.

Speaking from personal analysis and from the observation of others, I would say that general-chemical and physical knowledge may sometimes be as much a detriment as a help to one imbued *only* with a *need* of solving new problems. A possible explanation is this: We always reason deductively. We apply general laws in attempting to answer specific questions. To any specific problem of research there are usually general laws which may seem to forbid the solution. These laws are known and revered. Naturally, the unknown, specific ways by which it may be solved are more or less hidden An illustration may not be out of place here:

Cotton may be dissolved in a solution of zinc chloride. The solution may be squirted through a die into alcohol in such a way that a smooth, coagulated cellulose thread is thereby obtained. This may be heated so as to give a solid, compact and pure carbon filament. Many are thus made. But as a new problem, it would certainly appear quite impracticable to one who might have a fairly extensive knowledge of the chemistry of the materials. Generally speaking, zinc chloride solution does *not* dissolve cellulose. Only a strong solution, kept at a high temperature for a long time, will give the desired solution. In general, too, it could *not* be squirted and coagulated into a smooth thread. Very specific conditions are necessary. Finally, the treatment with gradually rising temperature, which alone succeeds in giving the compact carbon filament, is a matter of specific detail. The places in this process where general reasoning points to failure are numberless. Years of multiplied effort are necessary to perfect such a process. Once established, it is easily analyzed along the lines of understood reason and theories of reactions may be based upon the facts. But such processes are not laid out greatly in advance of their accomplishment. The successful steps are found among the many which are actually attempted, and something more than general knowledge is necessary. This something is hopeful pertinacity, optimistic activity. To a chemist imbued with fair knowledge, it was recently apparently useless to attempt such an experiment as the continual removal of traces of hydrogen from oxygen by passing the gas through a red-hot iron pipe. He had seen iron wire burned rapidly in oxygen, he tried wrought iron and the iron was oxidized, and his knowledge was vindicated, but he also tried cast iron and found that it did not burn and that it would operate perfectly. A scramble for an explanation evolved the theory that the silicon burning to silica protected the iron. *Ex. postfacto* theories are permissible.

As the mental world is constituted, optimists are greatly in the minority, when one counts those only who are also imbued with knowledge. Therefore, in practice, the optimist must be used to crystallize the efforts of others less optimistic. Thus, any large industrial research laboratory is soon *perforce*, systematized into organized clusters of people, working along distinct and different lines. This permits, in our case, of the combined use, to maximum efficiency, of the delicate hands of young women, the strength and skill of trained mechanics, the mind of the useful dreamer, the precision and knowledge of the skilful chemist, and the data of the accurate electrical engineer.

Simple mathematical axioms make clear the fact that a group of operators working together on a subject, are related to the same group operating separately, as a power is related to a simple sum. This principle holds as well among a group of groups and to related subjects. It is evident, for example, that knowledge gained along the line of insulation would be of use in a study of conduction, and that the man who had studied the reduction of tungstic oxide by carbon *in vacuo* could help the one who is working with a pressure furnace, upon the equilibrium between carbon monoxide and carbon dioxide. Therefore, the strength of a research department, properly operated, should rise exponentially with its numbers.

To this audience, the importance of highest advance in specific chemical and physical training will probably be apparent, but an expression of it may be of use. The supply of highly trained men is below the demand. There is a healthy supply of moderately trained men. This applies to all general, scientific training. Let me give more concrete ideas. There are a hundred chemists who can fill satisfactorily an analyst's position, to one who knows what J. J. Thomson has done or who reads Drude's *Annalen*. Reading the *Annalen* is not a "sine qua non," but it is an indicator of no little merit. If a chemist or a physicist is not sufficiently interested to keep informed, he is probably not going to work at high efficiency as an investigator. This does not preclude the possibility of splendid research work being done by some one who is confined to a very limited field of vision, but such cases are the exception and cannot be used as bases for common application. In general, the man with the best tools and with the best knowledge and experience in their use, will advance most rapidly in industrial research. In my own experience, we frequently have a line of work which demands the addition to the force of well trained men. The difficulty which stands out most markedly when considering this problem is usually the scarcity of men who are highly enough trained along the line of pure research. While in many fields of *industrial* research new and brilliant discoveries will continue to be made suddenly and, as it were, out of new cloth, still many more are being made by the most careful application of highly refined methods and knowledge, to processes which already seem at first pretty well worked out. This *intensive farming* is most promising and demands the highest skill. It is to-day most difficult to find American trained men who can do this work. It is a German attribute which we would do well to make our own.

If the chemist is only a chemist or the physicist confined to pure physics, he is liable to overestimation of the laws he learns. He should be something of a "mental mixer," one who has enough history, enough psychology, and enough faith to read possibility of acquirement for the future out of knowledge of attainments in the past.

As we have said, one of the most practical detriments to successful industrial research is that automatic action of the mind which recognizes the possible grounds for a failure quicker than it sees the probable ways to success. Research needs more aviators. Those of us who feel the work-horse brand on our work have a call to cultivate a *flying* spirit, and are to be condemned only if we stand still.

In this connection, I am in favor of anything which helps train the American student in the path of sanguine research. It can be done by research men themselves, but probably not by others. It is not the *knowledge* which the student preparing for research needs, so much as the spirit of the investigator. His thoughts should not be fettered by laws, but helped by them to fly. This can be done best by those who are optimistic almost to the extinction of reason.

A search in the research laboratories of the world to-day would disclose large numbers of J. J. Thomson men, Ostwald men, Nernst men, van't Hoff men The teacher probably made the school. The investigator probably endowed the students, not with facts alone, but with spirits. We are not of that hopeless class who assume that the sparks of genius are only Heaven-sent, but we are inclined to adopt as an axiom that man is flexible, auto-corrigible and mentally elastic beyond limit. Therefore the rare genius in research, as elsewhere, is the one most given to hopeful effort.

To dwell for a moment upon points in a system for co-operation of a research force, I will describe our own scheme.

The present corps comprises about eighty people, about thirty of whom are college men, mostly chemists. Every man or woman on the research staff is expected to give undivided effort to the work. Whatever invention results from his work becomes the property of the company. I believe that no other way is practicable. An attempt to reward systematically such labors by a scheme of royalty payment is more impracticable than the operation of a manufacturing plant upon a graded scheme of profit sharing. In this case an immediate and fairly equitable division of profits is sometimes possible. In research, the problem itself is an asset of the organization. Both the equipment and the risks belong to the organization. The accumulated experience of the force as a whole is its property. Finally, the privilege of directing the work of operators along lines where no direct financial benefit (or an immeasurable one) to the company could ever be determined, must belong to it. Every operator is expected to keep good notes and his books become a part of the laboratory files. In most cases weekly typewritten reports are made by each worker, and copies of these also become part of accessible library files. For purposes of establishment of dates, etc., witnesses who read and understand the notes also endorse them. Photographs of apparatus, curves, etc., are frequently added wherever useful, and each room of the laboratory is photographed regularly and the dated photographs are bound in books, to record standing conditions. Wherever practicable, single sheets, of standard report size, are printed to cover oft-repeating data, so that the experimenter regularly fills in certain blanks, as, for example, in experiments on carbon motor brushes: the composition of the particular lot, temperature and time of drying and firing, hardness, resistivity, tensile strength, and all other tests of the product. The use of plotted curves on standard millimeter paper, for use where one property of material is studied as a function of some other variable, is very common in our reports. This occurs, for example, in practically all cases where electric furnace work is described, and where the changes undergone by incandescent lamps during their life are recorded.

These conditions are the result of eight years of development. The system has been subjected to many changes and may still be greatly improved. It is possible to have such a complex system of record that efficiency is sacrificed. We have reached the present stage because of frequent indications of previous weakness in the simpler methods. Very few good investigators can keep good notes. The more interested the investigator becomes, the more difficult it seems for him to carefully record his passing work. His eyes and mind are always upon the exciting and more interesting advance. It seems not so tempting to actually make history by the writing as to metaphorically make it by the conception or experiment.

We now come to the material side of the subject.

In the early days, the same hands which mined the iron ore and operated the bellows, also forged the sword and plowshare and touched the goods which were the equivalent in exchange. The records of the development through which the distribution of the steps of such processes has gone is what we call the history of man. It is not always easy to recognize the extent to which this development is progressing in our own time. Statistics ought to show us, but these often fail to impress us. It may be that if used to a limited extent to armor an argument, a few data will be of interest in connection with industrial research.

The known chemical compounds of the earth are myriads. The still unknown, but knowable, are certainly many myriads more, but any consideration of either great mass is too huge a task. We may, however, consider for a moment a part of the alphabet from which that language is made. We will consider research as applied to the *metallic elements* alone.

There are about 75 elements. About two-thirds are metals. Of these, only a very few can be said to have been the subject of much industrial research. It is impossible to accurately measure the extent to which an element has been studied with a view to its possible use by the race, but we have no difficulty in recognizing that iron and copper have been much studied, while calcium and silicon have not. In these illustrations we have *not* selected *rare* elements. The calcium and silicon, which have been least used by man thus far, are more common than copper or iron. A natural explanation of the lack of development of such elements is a lack of need, but this is possibly incorrect. Copper, iron, etc., were certainly first obtained by accident as distinct from design. The uses to which they could be put were later developed by trial. The finding of some uses established the further supply, which insured the subsequent discovery of new uses. This mirrors the history now being made by new elements such as silicon. Only in the past year the commercial production of this element has been begun, and about 500 tons were sold for a deoxidizer in steel-making. Thus a substance absolutely out of reach of almost every chemist a few years ago, can now be obtained as cheaply as zinc.

Similarly, future needs, which only calcium, for example, can meet, are certain to be developed. More calcium will then be made. The cost of production will be reduced and the field of its usefulness will again and ever afterward continue to broaden. Never in the history of the world has the rate of iron production been so great as at present (nearly two million tons a month by the U. S. Steel Company alone). Copper is being mined more rapidly than ever before. We have ourselves seen the industrial birth and growth of a new metal which points to the great possibilities in case of the other unused elements. I refer to aluminium. Only two to three tons were made as late as 1884 while furnaces now exist which are capable of yielding three to four times this quantity every hour of the day and night. Its *present* uses could only have been, and were, very imperfectly predicted, before actual industrial research made tentative use of it. So it must be with other elements. One is not too bold who assumes that all the elements which are found in abundance will be industrially utilized when they have been economically isolated and thoroughly investigated.

I am considering the metallic elements only in order to point out in a concrete manner the need of high-quality research, physical, chemical, electrical, etc., in the *simplest* field. Evidently this field, among compounds of the elements, is again bounded only by the infinite. I am impressed with the idea that the commonest elements in nature have not been *studied* with anything like the care which has been given to those for which the demands are already developed.

In our age, a single investigator will probably not isolate, in large quantities, the metal tellurium, for example, and also put it to use to fill one of his individual needs, as did the warrior who first fashioned an iron blade or axe. The men who develop the myriad uses to which the common element titanium will be put, will have to rely upon the previous work of many investigators. It is in this respect that the conditions are continually changing, and always in one direction. I call it the direction of specific complexity. Our wants are very complex. We are learning to demand very specific properties. It is this fact which makes necessary the research work of the specialist, the specific or narrow investigation of the pure scientist, the pioneer work of the trail-blazer, the crude and hurried trials by the inventor, the long and exacting developments of the practical application in the factory, etc. Demands for new materials do not really precede the discovery of the product, any more than the demand for high-speed tool steel preceded the discovery of the properties of the chrome-tungsten-iron alloys. With the material discovered, its properties known, the world apparently could then hardly get along without it. This means that necessity is not the mother of invention. Knowledge and experiment are its parents. It sometimes happens that a successful search is made for unknown material to fill well recognized and predetermined requirements. It *more* often happens that the acquirement of knowledge of the previously unknown properties of a material suggests its trial for some new use. These facts strongly indicate the value of knowledge of properties of materials and indicate a way for research.

Among the recently developed uses for modern metals which were certainly not surmised until the metal itself had been made easily available, are the use of aluminium and silicon as deoxidizers in steel-making, where all the silicon and a large part of the aluminium are now used. This discovery of utility by experiment, rather than the discovery of material by *force of necessity*, is again illustrated by the metals titanium and vanadium. The former is used in arc lamps because it was found, by experiment, to give a good light. (Your Worcester streets are lighted by it.) The latter has been surprisingly useful in steel-making, where a fraction of 1 per cent. has been found to impart additional strength to the steel. In this way, about a thousand tons of vanadium are now used annually in America.

When the first step is taken from the study of the supply, production and utilities of our metallic elements, the next step is apparently along the lines of alloys and we readily see how quickly the field widens. The recent great advances in scientific foundation for much study are to be attributed to the physical chemists, to such men as Tamman and his school. In their work we begin to see the magnitude of the alloy field. There are probably over a *thousand pairs* of metals whose properties as alloys are still absolutely unstudied, and for alloys of three or more metals the number is legion.

It seems as though our advance could be quickened by a greater intimacy with the newly cheapened elements. When sodium, chlorine, bromine, silicon, magnesium, chromium, cobalt, manganese, tungsten, etc., etc., are many times as available or cheap as they were only ten years ago, it is probable that the possible uses are not up-to-date.

The field of material research really divides into two parts: the search for more economical production and the search for wider application. These two go hand in hand. If the one advances, the other is led along. In this way, in our laboratory, the knowledge of such elements as carbon, as in its forms of graphite in lamp filaments, in motor brushes, in electrodes, etc., has been widely and continually advanced. The result is not a conclusion that we know all about carbon, but rather that it still presents a wonderful field for useful research.

From the materials worked *upon*, to the tools is a step. Our experience here is concrete and clear, and we want to record our impressions. Good tools, new tools, rare tools, are most valuable. No good tool lives long for a single use alone. Many times we have questioned the advisability of installing some new apparatus—a vacuum furnace, a pair of metal rolls, some special galvanometer, some microscope, an hydraulic press, a power hammer, a steam digester, etc., etc. Never, after it became a part of the equipment, has it seemed possible to proceed without it. In the single case of the electric vacuum furnace, for example, our laboratory has made almost continual use of from three to eight for the past five years. The laboratory, piped several years ago with high vacuum and with electrolytic hydrogen, besides steam, air, water and gas, will probably never operate without them.

Similarly, this applies to a library. In general, the most useful and fertile of our investigators use the library the most. This is as it should be. The recorded research work in a library of a few thousand volumes frequently represents the work of millions of work-hours, and there is little excuse for not availing oneself of the published experience of others. A library containing ten of the leading research journals of the world may be said to have in each volume about 100,000 available brain-power-hours. So a library corresponds to a charged storage battery of great capacity.

RESEARCH LABORATORY, GENERAL ELECTRIC CO.,
SCHENECTADY, N. Y.

NOTE.

The Speedy Detection of Potassium in Small Amounts.—The use of sodium cobaltinitrite as a reagent for the detection of potassium has been known for a long time, but very little attention appears to have been given to its delicacy. Crookes[1] quotes De Koninck as saying that the precipitate is still formed at a dilution of 1/1000 KCl, but not at 1/2000. The writer also obtained by an indirect method the proportion of 1/1600 K_2O as the point at which precipitation would not occur.

A careful investigation of this reaction is given by W. C. Bray,[2] who finds the sensitiveness to be far greater than the above figures. During the course of a study of this reaction for quantitative purposes, the writer was fortunate enough to find a means of greatly shortening the time required for the test. Bray dissolves a given amount of potassium as potassium chloride in 5 cc. of water, adds a little acetic acid and 5 cc. of the sodium cobaltinitrite reagent (containing 0.5 g. Co in 100 cc.), then allows it to stand until there is a turbidity formed, afterward bringing the precipitate onto a white filter paper where it can be easily seen. The writer has found that if to the solution prepared as described there be added an equal volume of strong alcohol the precipitate will be formed in a very short time, so short in fact that if enough potassium is present to give a test at all it will by this means be thrown down in a few minutes, where several hours would be required otherwise. The following table shows the comparative times required by the procedure used by Bray and that where alcohol is added.

This shows that the sensitiveness of the reaction is not increased by the addition of alcohol, but that any potash that will be detected at all will be shown in a few minutes. A qualitative test, however, sensitive to 2/100,000 is unusual, and is really more accurate than needful in ordinary work

Particular care must be exercised to insure the removal of all ammonium salts previous to testing for potassium, since by the addition of alcohol they are thrown down as quickly as the latter, and almost as completely. This reagent gives a sensitiveness with ammonium salts of 5/100,000, making it not greatly inferior in point of delicacy to the Nessler reagent. Following is given a comparison of Bray's results on ammonium salts and mine where alcohol is added.

WOOSTER, OHIO.

CORRECTION.

My attention has been called to an error in the review of recent work in inorganic chemistry, which appeared in the December number of THIS JOURNAL. The statement is made that Keiser found the formula of the bicarbonates of calcium and barium to approach "closely the formula $H_2M(CO_3)_2$." As a matter of fact the bicarbonates analyzed contain considerably more carbonic acid than would correspond to this formula, being in the case of the calcium salt $CaCO_3.1.75H_2CO_3$, and in the case of barium $BaCO_3.1.5H_2CO_3$. The work should also have been attributed to Keiser and Leavitt, and Keiser and McMaster. JAS. LEWIS HOWE.

CHEMICAL EXAMINATION OF JALAP.[1]

BY FREDERICK B. POWER AND HAROLD ROGERSON.

Received November 8, 1909.

Under the title of *Jalapa* (Jalap) the various national Pharmacopoeias recognize the dried tuberous root of *Exogonium purga*, Bentham (*Ipomoea purga*, Hayne). The only constituent of the tuber possessing chemical interest is the resin, which is largely used medicinally. This resin (*Resina Jalapae* of the Pharmacopoeias), like many similar products obtained from plants belonging to the family of Convolvulaceae, is of a glucosidic nature. It has been the subject of numerous chemical investigations during the past century, and the literature relating thereto is therefore considerable in extent. A review of the more important of these publications has been given by Hoehnel[2] in connection with an investigation entitled "Ueber das Convolvulin, das Glycosid der Tubera Jalapae (*Ipomoea purga*, Hayne)." A quite complete account of this subject and of other closely related so-called glucoside resins, together with citations of the literature, have also been recorded by van Rijn ("Die Glykoside," Berlin, 1900), and by Tschirch ("Die Harze," Bd. II, Leipzig, 1906).

It would not be expedient in this place to consider in detail the various statements of earlier investigators respecting the composition of jalap resin or the products obtained therefrom, especially as many of these statements are not only conflicting, but are evidently based upon incorrect observations and deductions. In order, however, to indicate the unsatisfactory state of present knowledge respecting the chemical characters of this resin, a brief exposition of the subject may be given.

The chief portion of jalap resin, which is insoluble in ether and commonly designated as "convolvulin,"[3] although a completely amorphous product, has at various times been assigned the following empirical formulas: $C_{31}H_{50}O_{16}$ (Mayer); $C_{21}H_{35}O_{10}$ (Kayser); $C_{24}H_{40}O_{12}$ (Laurent);

---

[1] Communicated, in abstract, to the International Congress of Applied Chemistry, London, June 1, 1909. Presented at the meeting of the New York Section of the American Chemical Society, October 30, 1909.

[2] *Arch. Pharm.*, 234, 647 (1896).

[3] In English pharmacy the portion of jalap resin which is insoluble in ether is still frequently designated by the original and more appropriate name of "jalapin." The latter term, however, is now more commonly employed to denote the resin of scammony and of Mexican Male jalap (*Ipomoea orizabensis*, Ledanois), both of which are completely soluble in ether.

$C_{32}H_{62}O_{16}$ (Taverne); $C_{61}H_{108}O_{27}$ (Kromer); $C_{54}H_{96}O_{27}$ (Hoehnel). It has been stated by the last-mentioned investigator,[1] whose results alone need be somewhat further considered, that "convolvulin," when treated with bases, yields the following products: methylethylacetic acid; "purgic acid;" and "convolvulic acid." Purgic acid, which has been regarded as dibasic, and possessing the formula $C_{25}H_{46}O_{12}$, has been described as forming a yellowish, extremely hygroscopic, varnish-like mass, readily soluble in ether. Convolvulic acid, which is insoluble in ether, and was regarded as monobasic, was obtained as a white, amorphous powder, to which the formula $C_{45}H_{80}O_{28}$ was assigned. Both of these products were found to be glucosidic, the purgic acid, when heated with dilute mineral acids, having yielded a sugar, a product regarded as decylenic acid, $C_{10}H_{18}O_2$, and hydroxylauric acid, $C_{12}H_{24}O_3$, while convolvulic acid, by the same treatment, yielded a sugar and convolvulinolic acid, $C_{15}H_{30}O_3$. In the latter instance it was assumed that the hydrolysis might be represented by the following equation:

$$C_{45}H_{80}O_{28} + 5H_2O = 5C_6H_{12}O_6 + C_{15}H_{30}O_3$$

A consideration of the results obtained in the present investigation will doubtless render it evident that many of the conclusions which have previously been recorded respecting the composition of jalap resin and various amorphous products obtained therefrom are erroneous. In the first place, it would be quite fallacious to assign to the so-called "convolvulin" any empirical formula whatsoever, inasmuch as we have shown that by successive extraction with various solvents, such as chloroform, ethyl acetate, and alcohol, it may be further resolved into several products, all of which, moreover, are amorphous and of indefinite composition. Similar conditions exist with regard to the character of the amorphous products obtained by the alkaline hydrolysis of the resin, such as the so-called "purgic" and "convolvulic" acids, to which empirical formulas have likewise been assigned. Both of the last-mentioned products are complex mixtures, some of the constituents of which are not even glucosidic. We have shown, for example, that the alcohol extract of the resin, when hydrolyzed by baryta, yields a product which, like the original resin, is capable of being further resolved when successively extracted with ether, chloroform, ethyl acetate, and alcohol. The last-mentioned alcohol extract, when heated with dilute sulphuric acid, affords, moreover, not only sugar and convolvulinolic acid, $C_{15}H_{30}O_3$, as indicated by Hoehnel in the case of a less completely purified product, but also ipurolic acid, $C_{14}H_{28}O_4$, and several volatile acids, while a portion of it apparently remains unchanged. It is thus obvious that the "convolvulic acid" of Hoehnel can not be regarded as an individual substance, nor can its degradation be represented in the manner suggested by him.

---

[1] *Loc. cit.*

Notwithstanding the numerous investigations of jalap resin, it will be apparent from the observations above noted that the statements concerning its composition and character are not only widely divergent, but that in many respects they are based upon quite erroneous assumptions. It has therefore been deemed desirable to subject this resin to a more complete examination, and the results of the present research are summarized at the end of this paper.

Experimental.

The material employed in this investigation consisted of an original bale of Jalap tubers of good quality, as indicated by the percentage yield of resin when assayed by the methods described below.

As a preliminary experiment, 50 grams of the finely ground material, representing an average sample of 75 kilograms of the drug, were successively extracted in a Soxhlet apparatus with various solvents, whereby the following amounts of extract, dried at 100°, were obtained.

	Gram.		Per cent.
Petroleum (b. p. 40–60°) extracted	0.19	=	0.38
Ether "	0.34	=	0.68
Chloroform "	0.27	=	0.54
Alcohol "	5.90	=	11.80
Water "	11.15	=	22.30
Total,	17.85	=	35.70

Determination of Total Resin.—I. The first method employed in this determination was essentially that of the British Pharmacopoeia. Fifty grams of the finely ground material were thoroughly extracted in a Soxhlet apparatus with hot alcohol (94 per cent.). To the liquid thus obtained 25 cc. of water were added, and the alcohol removed by distillation, after which the residue was brought into a dish and heated on a water bath in order to remove the last traces of alcohol. The separated resin was then thoroughly washed with hot distilled water, and finally dried in a water oven until of constant weight. Two concurrent determinations yielded 4.7 grams of resin, corresponding to 9.4 per cent. of total resin in the drug. The proportion of this crude resin which was soluble in ether, as determined by its complete extraction in a Soxhlet apparatus, corresponded to 11.6 per cent. of its weight.

II. The second method employed for the determination of the resin was that of the United States Pharmacopoeia (eighth revision), which, however, as in the preceding method, was modified by conducting the extraction of the drug in a Soxhlet apparatus. The amounts of resin, representing the ether extract and the portion insoluble in ether, were

1.0 and 9.5 per cent. respectively, the total resin being thus 10.5 per cent. of the weight of the drug.

It will be observed that the results obtained by the two above-mentioned methods of assay differ appreciably, as might be expected, but the relative merits of these methods need not be here discussed.

Extraction of the Jalap with Hot Alcohol and Distillation of the Extract with Steam.—For the purpose of a complete examination of the drug, 75 kilograms of the ground material were completely extracted with hot alcohol. After the removal of the greater portion of the alcohol, 23.8 kilograms of a soft extract were obtained. A quantity of this extract was brought into a large flask, some water added, and the mixture distilled with steam until volatile products ceased to pass over. A distillate was thus obtained, which contained some oily drops floating on the surface. After this operation there remained in the distilling vessel a dark colored, aqueous liquid (*A*) and a quantity of soft resin (*B*). The resin was repeatedly washed with warm water until the latter remained colorless, and the washings added to the aqueous liquid.

Examination of the Steam Distillate. Separation of an Essential Oil.

The distillate obtained as above described was extracted with ether, the ethereal liquid being dried with anhydrous sodium sulphate and the solvent removed. A very small amount (2.4 grams) of an essential oil was thus obtained, which, when distilled under diminished pressure, passed over between 80 and 160°/60 mm. This oil, when freshly distilled, had a pale yellow color, but became very dark on standing. It possessed a disagreeable and persistent smoky odor. A dilute alcoholic solution of the oil gave with ferric chloride a deep brownish red color. Its density was 0.8868 at 20°/20°, and it was optically inactive.

Examination of the Aqueous Liquids (A).

The aqueous liquid remaining in the distillation flask, after the above-described treatment with steam, was separated from the resin, and, together with the washings from the latter, evaporated to a small volume. As the dark colored sirup thus obtained deposited nothing on standing, it was diluted with water, and a solution of basic lead acetate added until no further precipitate was produced.

Basic Lead Acetate Precipitate.—This was collected, thoroughly washed with water, and then suspended in water and decomposed by hydrogen sulphide. After filtration, the liquid was concentrated, and shaken with several successive portions of ether. The combined ethereal liquids were repeatedly extracted with a solution of sodium carbonate, and subsequently with a 10 per cent. solution of sodium hydroxide. The first sodium carbonate extracts were dark in color and showed a blue fluorescence. They were acidified and extracted with ether, but the ethereal liquid, on evaporation, yielded only a small amount of an uncrystallizable sirup, which, however, developed with ammonia a blue fluorescence, and gave with ferric chloride a dark green coloration. This fluorescence was evidently due to the presence of a little β-methylaesculetin, a substance which was subsequently isolated in small amount from the chloroform extract of the resin. The extract obtained by means of sodium hydroxide had a dark red color. It was acidified and extracted with ether, but yielded nothing definite.

Filtrate from the Basic Lead Acetate Precipitate.—This was treated with hydrogen sulphide for the removal of the lead, the mixture filtered, and the filtrate concentrated under diminished pressure. It was then repeatedly shaken with ether, and the combined ethereal liquids extracted with several successive portions of aqueous sodium carbonate. The first sodium carbonate extracts had a red color and showed a blue fluorescence. When acidified, and again extracted with ether, a small amount of a sirup was obtained, which deposited a trace of a crystalline substance, but not sufficient to permit of its identification. The sirupy product developed with ammonia a blue fluorescence, and gave with ferric chloride a violet coloration. The ethereal liquid, after extraction with sodium carbonate, was shaken with a 10 per cent. solution of sodium hydroxide, when a dark red, aqueous liquid was obtained. This, however, when acidified and again extracted with ether, yielded nothing definite. The ethereal liquid, which had been completely extracted with the above-mentioned alkalis, was finally dried with calcium chloride and the solvent removed, but only a small amount of a dark red sirup was obtained.

The aqueous liquid which had been extracted with ether, as above described, contained a quantity of sugar, since it readily reduced Fehling's solution and yielded *d*-phenylglucosazone, which, after recrystallization from dilute pyridine, melted at 217–218°. For the further examination of the aqueous liquid it was concentrated to the consistency of a sirup, which, after dilution with alcohol, was mixed with purified sawdust, and the thoroughly dried mixture then successively extracted in a Soxhlet apparatus with chloroform, ethyl acetate, and alcohol. The first two solvents removed but a relatively small amount of material, the larger proportion being subsequently extracted by the alcohol. These extracts were all of a sirupy nature, and, although exhaustively examined, nothing crystalline could be separated from them. They were observed to contain, besides sugar, traces of the fluorescent principle previously referred to, which was evidently β-methylaesculetin.

Examination of the Resin (B).

This product, which had been obtained from the alcoholic extract of the drug as previously described, corresponds to the *Resin of Jalap* of the various national Pharmacopoeias.

Optical Rotation of the Crude Resin.

It has been indicated by P. Guigues[1] that the specific optical rotatory power of certain convolvulaceous resins is a factor which may be utilized for discriminating between them, and for the detection of substitutes and adulterants. This factor was therefore determined for the resin employed in the present investigation with the following result. A quantity of the crude resin was dissolved in 50 cc. of alcohol, and the solution boiled with successive, small portions of animal charcoal until it became practically colorless. The rotation of this liquid in a 1 dcm. tube was α_D —2° 0′, and the amount of substance contained in 10 cc. of the liquid, after drying at 105–110°, was 0.5400, hence $[\alpha]_D$ —37.0°. This result is in fairly close agreement with the figures recorded by Guigues and by Cowie[2] for a decolorized jalap resin, which are $[\alpha]_D$ —36.0 and —37.3° respectively.

Preliminary Extraction of the Crude Resin with Different Solvents.

In order to ascertain the general character of the crude resin, a weighed amount (about 5 grams) was dissolved in alcohol, mixed with purified sawdust, and the thoroughly dried mixture extracted successively in a Soxhlet apparatus with various solvents The percentages of extract, dried at 110°, were as follows:

I.	Petroleum (b. p 40–60°)	extracted	1.9
II.	Ether	"	9.7
III	Chloroform	"	24.1
IV.	Ethyl acetate	"	22.0
V	Alcohol	"	38.8
		Loss,	3.5
			100.0

For the purpose of a complete examination of the constituents of the resin, a large quantity of the crude material was employed. This was dissolved in alcohol, mixed with purified sawdust, and the thoroughly dried mixture extracted first with ethyl acetate, and subsequently with alcohol. The alcohol extract was then again extracted with ethyl acetate in a similar manner, after which the undissolved material was removed by means of alcohol, this portion being designated as the "alcohol extract of the resin." The entire amount of material removed by ethyl acetate was then mixed with a large quantity of purified sawdust, and the mixture thoroughly dried, after which it was submitted to prolonged successive extractions with petroleum (b. p. 40–60°), ether, chloroform, and ethyl acetate. The extracts obtained by these various solvents, together with the above-mentioned alcohol extract, were then separately investigated.

[2] *Loc. cit.*

I. *Petroleum Extract of the Resin.*

This extract, after the removal of the solvent, was a very dark colored soft solid. The amount employed for the investigation of its acidic constituents was about 60 grams, but for the examination of the non-saponifiable constituents an additional 60 grams was used.

The extract was dissolved in a large volume of ether, and the ethereal liquid extracted with two successive portions of aqueous sodium carbonate. These alkaline liquids, which possessed a deep red color, were separately acidified, again extracted with ether, and the solvent removed. The product from the first extraction (*a*) amounted to about 12 grams, and that from the second extraction (*b*) to 3 grams. When distilled under diminished pressure, they both passed over for the most part between 220 and 240°/25 mm., and solidified on cooling to a white, crystalline mass. They were then recrystallized from ethyl acetate, and finally from glacial acetic acid, when the product (*a*) melted at 58–60° and the product (*b*) at 60–62°. These products consisted of saturated acids, and they were analyzed with the following results:

(*a*) 0.1804 gave 0.4974 CO_2 and 0.2008 H_2O. C = 75.2; H = 12.4
(*b*) 0.1454 gave 0.4024 CO_2 and 0.1620 H_2O. C = 75.5; H = 12.4
$C_{16}H_{32}O_2$ requires C = 75.0; H = 12.5 per cent.
$C_{18}H_{36}O_2$ requires C = 76.1; H = 12.7 per cent.

It would thus appear that the above-mentioned products consisted chiefly of a mixture of palmitic and stearic acids, the former predominating.

The ethereal liquid which had been extracted with sodium carbonate, as above described, was subsequently shaken with a 10 per cent. solution of sodium hydroxide. This alkaline liquid had a deep red color. It was acidified and extracted with ether, when, after removing the solvent, a small amount of a sirupy product was obtained. The latter deposited a little of a substance in the form of rosettes of needles, which melted at 205–206°, but the amount was too small for further examination.

The ethereal liquid, after extraction with sodium carbonate and hydroxide, was washed with water, dried, and the solvent removed. The residual product, which amounted to 35 grams, was hydrolyzed by heating in a reflux apparatus for several hours with an alcoholic solution of potassium hydroxide. The alcohol was then removed, water added, and the mixture shaken with ether. As an inseparable emulsion was thus formed, the mixture was made slightly acid, then completely extracted with ether, and the ethereal liquid shaken with a solution of sodium carbonate. This alkaline liquid was acidified, and distilled with steam, when a distillate was obtained which contained a few oily drops floating on the surface. The distillate was extracted with ether, the ethereal liquid being dried and the solvent removed, when a small amount of an oily acid was obtained. This was converted into a silver salt, and the latter analyzed.

0.1280 of salt gave on ignition 0.0560 Ag. Ag = 43.7.

$C_8H_{15}O_2Ag$ requires Ag = 43.0 per cent.

Although the figures thus obtained are in fairly close agreement with those required for the silver salt of an octoic acid, it is possible that the oily acid was a mixture.

The distillate, after extraction with ether, was found to contain small amounts of formic and butyric acids.

After the removal of the volatile acids by distillation, as above described, the contents of the distillation flask were extracted with ether, the ethereal liquid being washed, dried, and the solvent removed. A small amount (about 2 grams) of an oily product was thus obtained, which became partially solid. By converting this product into a lead salt, and treating the latter with ether, an approximate separation of the acids was effected. The portion of lead salt which was soluble in ether yielded, after treatment with sulphuric acid, 0.6 gram of a dark orange-colored oil. This was unsaturated, and a determination of its iodine value gave the following result:

0.5328 absorbed 0.7601 iodine. Iodine value = 142.6.

$C_{18}H_{34}O_2$, with one ethylenic linking, requires I = 90.0 per cent.

$C_{18}H_{32}O_2$, with two ethylenic linkings, requires I = 181.4 per cent.

The oily acid therefore appears to have consisted largely of linolic acid.

The portion of lead salt which was insoluble in ether yielded 1.2 grams of solid acid, which distilled at 220–230°/15 mm., and, after recrystallization from glacial acetic acid and ethyl acetate, melted at 62°. This evidently consisted of palmitic acid.

Unsaponifiable Constituents of the Petroleum Extract.

Isolation of a Phytosterol, $C_{27}H_{46}O$, and Cetyl Alcohol.

As noted above, the portion of the petroleum extract which was insoluble in a solution of sodium carbonate and sodium hydroxide was hydrolyzed, the product acidified, extracted with ether, and the ethereal liquid shaken with a solution of sodium carbonate. After this treatment the ethereal liquid was washed, dried, and the solvent removed, when an oily product was obtained which solidified on cooling. This was dissolved in alcohol, and the solution concentrated, when, after standing for some time, a quantity of a substance was deposited in the form of large, colorless plates. After recrystallization from a mixture of ethyl acetate and dilute alcohol, it separated in flattened needles, which melted at 134–135°.

0.1148 of the air-dried substance, when heated at 110°, lost 0.0054 H_2O.
H_2O = 4.7.
0.1094 of anhydrous substance gave 0.3360 CO_2 and 0.1180 H_2O.
C = 83.8; H = 12.0.
$C_{27}H_{46}O$, H_2O requires H_2O = 4.5 per cent
$C_{27}H_{46}O$ requires C = 83.9; H = 11.9 per cent.

The substance thus agrees in composition with a phytosterol, and it gave the color reactions yielded by this class of substances.

The optical rotatory power of the phytosterol was determined with the following result:

0.1349 of anhydrous substance, dissolved in 25 cc. of chloroform, gave in a 2 dcm. tube a_D —0°21′, whence $[\alpha]_D$ - 32.4°.

A small amount of the phytosterol was converted into its acetate, which separated from its solution in acetic anhydride in leaflets, melting at 119–120°.

The mother liquor from the phytosterol was evaporated, and the residue distilled under 15 mm. pressure, when the following fractions were eventually obtained: (I) Below 180°; (II) 180–190°; (III) 190–200°; (IV) 200–225°; (V) 225–250°; (VI) 250–300°; (VII) 300–320°/15 mm. The first four of these fractions contained a crystalline solid. This was collected and recrystallized several times, first from light petroleum and then from ethyl acetate. It was thus obtained in small leaflets, melting at 50–51°, and was analyzed.

0.1114 gave 0.3230 CO_2 and 0.1434 H_2O. C = 79.1; H = 14.3.
$C_{16}H_{34}O$ requires C = 79.3; H = 14.1 per cent.

This substance was thus identified as cetyl alcohol.

The above-mentioned fractions (V) and (VI) were of an oily nature, and yielded nothing definite, whereas fraction (VII), on standing for a long time, deposited a small amount of a crystalline substance. This was separated, and recrystallized from ethyl acetate, when it formed glistening leaflets, melting at 56–57°. It yielded color reactions similar to those given by the phytosterols. After further crystallization from ethyl acetate, and finally from absolute alcohol, its melting point and properties remained unchanged. The substance was then analyzed.

0.0986 gave 0.2906 CO_2 and 0.1230 H_2O. C = 80.4; H = 13.9.
$C_{18}H_{36}O$ requires C = 80.6; H = 13.4 per cent.

The composition of this substance is thus seen to agree with the formula $C_{18}H_{36}O$, and, as it differs in its properties from any substance of this formula which has hitherto been described, it would appear to be a new compound. The amount of substance, however, was too small to admit of this conclusion being confirmed.

The liquid portion of fraction (VII), from which the above-described solid had been separated, was stirred with slightly diluted alcohol, when it deposited a further quantity of phytosterol, identical with that previously obtained.

II. *Ether Extract of the Resin.*

This extract, after the removal of the solvent, was a very dark colored, soft solid. The amount employed for its investigation was about 200 grams.

Isolation of a New, Dihydric Alcohol, Ipurganol, $C_{21}H_{32}O_2(OH)_2$.

During the process of extracting the resin with ether it was observed that a small amount of a solid substance was deposited from the ethereal liquid. This was collected, and purified by extracting it in a small Soxhlet apparatus with absolute alcohol, when it was obtained perfectly white. It was subsequently crystallized from dilute pyridine, when it separated in clusters of very small needles, melting at 222–225°. The amount of this substance obtained from 200 grams of the ether extract was about 4.5 grams. On analysis it gave the following result:

0.1047 gave 0.2752 CO_2 and 0.0946 H_2O. C = 71.7; H = 10.0.
$C_{21}H_{34}O_4$ requires C = 72.0; H = 9.7 per cent.

This substance would thus appear to possess the formula $C_{21}H_{34}O_4$, and, so far as known to us, no substance of this formula has hitherto been described. It is therefore to be regarded as a new compound, and, with reference to the source from which it has been obtained and its alcoholic nature, it is proposed to designate it *ipurganol.*

The optical rotatory power of ipurganol was determined with the following result:

0.1760 of substance, dissolved in 25 cc. of pyridine, gave in a 2 dcm. tube, α_D—0.6333°, whence $[\alpha]_D$ —44.9°.

A portion of ipurganol was heated with acetic anhydride for about 2 hours, when, on cooling, a crystalline product was obtained. This was recrystallized from ethyl acetate, from which it separated in fine, colorless needles, melting at 166–167°.

0.0898 gave 0.2268 CO_2 and 0.0714 H_2O. C = 68.9; H = 8.8.
$C_{21}H_{32}O_4(CH_3.CO)_2$ requires C = 69.1; H = 8.7 per cent.

This substance is thus seen to be *diacetylipurganol*, and affords evidence of the presence in ipurganol of two hydroxyl groups.

The optical rotatory power of diacetylipurganol was determined with the following result:

0.3132 of substance, dissolved in 25 cc. of pyridine, gave in a 2 dcm. tube α_D —0.902°, whence $[\alpha]_D$ —36.0°.

An attempt to prepare a methyl derivative of ipurganol was not successful.

Ipurganol yields color reactions which are similar to those given by the phytosterols. Thus, if the substance be dissolved in chloroform with a little acetic anhydride, and a drop of concentrated sulphuric acid subsequently added, a purplish pink coloration is first produced, which changes to blue, then to bright green, and finally becomes brown.

If concentrated sulphuric acid be added to ipurganol, the latter is colored deep reddish brown, while the acid soon acquires a yellow color with a green fluorescence.

In connection with the above description of ipurganol, it may be noted that it appears to be closely related to two substances of alcoholic nature which have quite recently been isolated in these laboratories. One of these was obtained from the resin of *Grindelia camporum*, Greene,[1] and agrees in composition with the formula $C_{28}H_{38}O_4$. It melts at 256–257°, and yields an acetyl derivative melting at 161°. This compound, which was not previously named, may now conveniently be designated as *grindelol*. The other substance was obtained from the resin of watermelon seeds, and has been designated *cucurbitol*. It possesses the formula $C_{24}H_{40}O_4$, melts at 260°, and yields an acetyl derivative melting at 150°. The three substances show slight differences in their color reactions when subjected to the above-mentioned test in chloroform solution with acetic anhydride and concentrated sulphuric acid. Thus grindelol and cucurbitol give at first a blue color, changing to dull green, and finally becoming brown, the intermediate greenish tint being less pronounced in the case of the last-mentioned substance. In view of the composition and character of these three new compounds, it is evident that they are members of a homologous series, which is represented by the general formula $C_nH_{2n-8}O_4$.

Treatment of the Ether Extract with Alkalis.

I. *Extraction with Ammonium and Sodium Carbonates.*—The ethereal solution of the ether extract, from which the ipurganol had been removed, as above described, was successively extracted with solutions of ammonium carbonate and sodium carbonate. This treatment, however, removed only small amounts of black resin. The ethereal liquid was then shaken with several successive portions of water, which removed a quantity of the sodium compound of a resin. These aqueous liquids were united and acidified, when the resin was precipitated, after which it was extracted with ether, the ethereal liquid being dried and the solvent removed. The large quantity (70 grams) of resinous material thus obtained was dissolved in alcohol, treated with animal charcoal, and the filtered liquid concentrated and allowed to stand for some time. As nothing could be separated by this means, the small amount of resin which had previously been extracted by sodium carbonate and treated in the same manner as the last-mentioned product was added to the alcoholic solution of the latter, together with such an amount of sulphuric acid as to represent about 5 per cent. of the mixture. The whole was then heated in a reflux apparatus for about 6 hours, after which water was added and the alcohol removed. The aqueous, acid liquid, from which a quantity of a soft resin had separated, was subsequently distilled with steam until volatile products ceased to pass over. The distillate, which contained some yellow, oily drops, was extracted with ether, and the ethereal liquid shaken with a solution of sodium carbonate. This alkaline, aqueous liquid was acidified, extracted with ether, and the solvent removed, when a small amount (0.4 gram) of an oily acid was obtained. The latter was converted into an ammonium salt, from which by precipitation with silver nitrate two fractions of a silver salt were prepared, and these were analyzed.

---

[1] *Proc. Am. Pharm. Assoc.*, 55, 342 (1907).

I. 0.2138 of salt gave on ignition 0.0734 Ag. Ag = 34.3
II. 0.1060 of salt gave on ignition 0.0410 Ag. Ag = 38.7
$C_{12}H_{23}O_2Ag$ requires Ag = 35.2 per cent.; $C_{10}H_{19}O_2$ Ag requires Ag = 38.7 per cent.

The ethereal liquid which had been shaken with sodium carbonate was dried, and the solvent removed, when a small quantity (1.5 grams) of a neutral, oily liquid was obtained. This was distilled under diminished pressure, when it passed over between 90 and 160°/15 mm. It gave no coloration with ferric chloride, but responded to the test for furfural.

The above-mentioned distillate, after extraction with ether, was found to contain small amounts of formic and butyric acids.

After the removal of the volatile products of hydrolysis by distillation with steam, as above described, there remained in the distillation flask a reddish-colored, aqueous liquid, and a soft, resinous mass which floated on the surface. The whole was shaken with ether, when the resinous material became completely dissolved. On subsequently extracting the ethereal liquid with sodium carbonate, about 3 grams of amorphous, dark colored resin were removed. The ethereal liquid was then dried, and the solvent evaporated, when 2 grams of a dark reddish-colored oil were obtained, which distilled between 210 and 250° under 15 mm. pressure. This oil separated no solid on standing. It gave a greenish yellow color with ferric chloride, and absorbed bromine in chloroform solution, but no definite product could be obtained from it.

The aqueous liquid which remained in the distillation flask after the removal of the volatile products of hydrolysis, and from which the soft, resinous mass had been separated, was treated with baryta for the removal of the sulphuric acid, and filtered. It then reduced Fehling's solution, but an attempt to prepare an osazone from it was not successful.

II. *Extraction with Sodium Hydroxide.*—After the treatment of the ethereal solution of the ether extract with ammonium and sodium carbonates it was shaken with two successive portions of a 10 per cent. solution of sodium hydroxide, and finally washed with water. The liquids thus obtained, which were dark in color, were acidified and extracted with ether, when it was observed that a small amount of a solid substance was deposited. This was found to consist of ipurganol, for, when treated with acetic anhydride, it yielded diacetylipurganol, melting at 166–167°. On subsequently evaporating the ethereal liquid a quantity (50 grams) of dark colored, resinous material was obtained, which possessed a somewhat disagreeable odor. As nothing could be separated from this resin, it was dissolved in alcohol, and a little water added, together with such an amount of sulphuric acid as to represent about 5 per cent. of its weight. The mixture was then heated in a reflux apparatus for 4 hours, after which water was added, the alcohol evaporated, and steam passed through the mixture until all the volatile products had been removed. The distillate, which contained some oily drops floating on the surface, was extracted with ether, and the ethereal liquid shaken with a solution of sodium carbonate. This alkaline, aqueous liquid was acidified, extracted with ether, and the solvent removed, when a small quantity of an oily acid was obtained. The latter was converted into an ammonium salt, from which a silver salt was prepared and analyzed.

0.2954 of salt gave on ignition 0.1026 Ag. Ag = 34.7
0.0658 of salt gave on ignition 0.0224 Ag. Ag = 34.0
$C_{12}H_{23}O_2$ Ag requires Ag = 35.2 per cent.

The ethereal liquid which had been shaken with sodium carbonate was dried, and the solvent removed, when a small quantity (about 3.5 grams) of a neutral yellowish oil was obtained. This was distilled under diminished pressure, when it passed over between 90 and 180°/20 mm., and was evidently a complex mixture.

The above-mentioned distillate, after extraction with ether, was found to contain small amounts of formic and butyric acids.

After the removal of the volatile products of hydrolysis, as above described, there remained in the distillation flask an aqueous, acid liquid, together with a cake of solid substance. The whole was shaken with ether, when the solid substance became completely dissolved. The ethereal liquid was extracted with sodium carbonate, which removed a quantity of soft, resinous material, after which it was dried, and the solvent removed. A quantity of a light colored oil was thus obtained, which solidified on cooling, and when distilled under diminished pressure passed over for the most part between 200 and 210°/25 mm. In order to ascertain its character, it was heated for a short time with an alcoholic solution of potassium hydroxide, and the liquid poured into water, when about 2 grams of a solid substance separated. This was extracted with ether, the ethereal liquid being dried and the solvent removed, when a residue was obtained which, after several crystallizations from light petroleum, melted at 49–50°.

0.1592 gave 0.4614 CO_2 and 0.2024 H_2O. C = 79.0; H = 14.1.
$C_{16}H_{34}O$ requires C = 79.3; H = 14.1 per cent.

This substance was thus identified as cetyl alcohol, which had also been obtained from the petroleum extract of the resin.

The aqueous liquid which remained in the distillation flask after the removal of the volatile products of hydrolysis, and which had been extracted with ether, was subsequently treated with baryta for the removal of the sulphuric acid. The filtered liquid, when concentrated, yielded a very small amount of a sirup, but this did not reduce Fehling's solution, and therefore contained no sugar.

The ethereal solution of the original ether extract, after being treated with alkalis, as above described, was dried, and the solvent removed. About 10 grams of a light-colored, viscid product were thus obtained, from which a very small amount of a phytosterol was separated.

III. Chloroform Extract of the Resin.

This extract, after the removal of the solvent, was a hard, dark reddish brown mass, which could be reduced to a light brown powder. The amount employed for its investigation was about 350 grams.

Treatment with Sodium Carbonate.

Isolation of β-Methylaesculetin, $C_9H_5(CH_3)O_4$.

As the solution of the extract in chloroform deposited nothing on standing, it was shaken with a solution of sodium carbonate, when a large quantity of a thick, dark brown, tarry product was formed, consisting of the sodium compound of an acidic resin. The chloroform liquid had then become nearly deprived of color, and was found to contain only a small amount of resinous material, while the aqueous, alkaline liquid was dark in color and showed a marked blue fluorescence.

The above-mentioned, tarry product was washed several times with a solution of sodium carbonate. These washings, together with the sodium carbonate extract first obtained, were acidified, when a small quantity of an amorphous, brown solid separated, which was removed by filtration. The acid filtrate was extracted with ether, the ethereal liquid being dried, and the solvent removed, when a small quantity of a sirup was obtained which, after long standing, deposited a crystalline substance. This was collected, and recrystallized from ethyl acetate, from which it separated in nearly colorless needles, melting at 200–202°. The solution of this substance, on the addition of a little ammonia, displayed a fine blue fluorescence. As the amount was too small for analysis, it was heated with acetic anhydride, when it yielded an acetyl derivative melting at 176°. This melting point remained unchanged when the acetylated substance was mixed with acetyl-β-methylaesculetin prepared from the respective compound isolated from the bark of *Prunus serotina.*[1] The identity of the above-described, crystalline substance (m. p. 200–202°) with β-methylaesculetin was therefore definitely established.

Treatment of the Sodium Compound of the Resin with Dilute Alcoholic Sulphuric Acid.

The large quantity of thick, dark brown, tarry product above referred to was dissolved in alcohol, a slight excess of sulphuric acid added, and the mixture poured into water. The liberated resin was then taken up with chloroform, and the solvent removed, after which it was dissolved in alcohol. To this solution some water was added, and such an amount of sulphuric acid that the latter represented about 5 per cent. of the weight of the mixture. This was subsequently boiled in a reflux apparatus for about 12 hours, after which water was added, the alcohol removed, and the mixture distilled with steam until volatile products ceased to pass over. The distillate, which contained some oil floating on the surface, was completely extracted with ether, and the ethereal liquid shaken with a solution of sodium carbonate, after which it was dried and the solvent removed. A neutral, oily product was thus obtained, but it was found to be a mixture, and the amount was too small for its further examination.

The above-mentioned sodium carbonate extract of the volatile product was acidified and extracted with ether, the ethereal liquid being dried and the solvent removed, when 1.5 grams of an oily acid were obtained. This distilled for the most part between 174 and 178° under the ordinary pressure, and was analyzed.

0.1258 gave 0.2702 CO_2 and 0.1128 H_2O. C = 58.6; H = 10.0.
$C_5H_{10}O_2$ requires C = 58.8, H = 9.8 per cent.

This acid was dextrorotatory, and was thus identified as *d*-methylethylacetic acid, which is stated to boil at 175°.

The remainder of this liquid, together with a portion of somewhat higher boiling point, was converted into a silver salt. This was obtained in two fractions, both of which were analyzed.

I. 0.3256 of salt gave on ignition 0.1678 Ag. Ag = 51.5
II. 0.4332 of salt gave on ignition 0.2244 Ag. Ag = 51.8
$C_5H_9O_2Ag$ requires Ag = 51.7 per cent.

The above-mentioned aqueous distillate, after extraction with ether, was found to contain small amounts of formic and butyric acids.

After the removal of the volatile products of the acid hydrolysis by distillation with steam, as above described, there remained in the distillation flask an acid liquid, together with a soft, resinous mass. The liquid was decanted from the resin and extracted with ether, which, however, removed only a small amount of an oily product. It was then treated with baryta for the removal of the sulphuric acid, filtered, and concentrated. A sirup was thus obtained, which readily yielded *d*-phenylglucosazone, melting at 210–211°. It was therefore evident that at least a portion of the chloroform extract of jalap resin was glucosidic.

---

[1] *J. Chem. Soc.*, 95, 256 (1909).

The previously mentioned, soft, resinous mass, which had been separated from the acid, aqueous liquid, as above described, was treated with hot ether, in which the greater portion was soluble. The ethereal solution was separated from the insoluble material, consisting of a black, hard resin, and extracted with a solution of sodium carbonate, after which it was dried, and the solvent removed. About 5 grams of a sirupy product were thus obtained, which was distilled under diminished pressure, when it passed over quite constantly at 210–211° as a lemon-yellow oil. This oil solidified on cooling to a white, crystalline mass, which was first dried on a porous plate and finally in a desiccator, when it melted at 23–25°.

0.0850 gave 0.2204 CO_2 and 0.0926 H_2O. C = 70.7; H = 12.1.
$C_{17}H_{34}O_3$ requires C = 71.3; H = 11.9 per cent.

This substance was evidently the *ethyl ester of convolvulinolic acid*, $C_{15}H_{29}O_3.C_2H_5$, and its formation during the treatment of the acidic portion of the chloroform extract with alcoholic sulphuric acid may be attributed to the amount of water present not having been sufficient to entirely prevent esterification. It agrees in character with the ethyl convolvulinolate prepared by Hoehnel,[1] which is stated to melt at 22.5°.

The sodium carbonate extract of the ethereal liquid from which the ethyl convolvulinolate was obtained was acidified and extracted with ether, the ethereal liquid being dried and the solvent removed, when it yielded a quantity of a dark colored sirup, which became partially solid on standing. This sirup was dissolved in alcohol, brought onto purified sawdust, and the thoroughly dried mixture extracted successively in a Soxhlet apparatus with light petroleum and ether.

Petroleum Extract:—This was a dark, orange colored sirup, which solidified to a soft, fat-like mass. It was distilled under diminished pressure, and the following fractions collected: (I) Below 220°; (II) 200–225°; (III) 225–230°; (IV) 230–290/15 mm. As no crystalline acid could be obtained from these fractions, they were converted into silver salts, and the latter analyzed.

From these results it is evident that the above-described petroleum extract was a mixture. It undoubtedly contained some convolvulinolic acid, $C_{15}H_{30}O_3$, and apparently also a higher homologue of the latter.

[1] *Arch. Pharm.*, 234, 677 (1896).

Fraction I.	0.3474 of salt gave on ignition 0.1124 Ag.	Ag = 32.4
Fraction II (a).	0.2032 of salt gave on ignition 0.0572 Ag.	Ag = 28.1
Fraction II (b).	0.2094 of salt gave on ignition 0.0594 Ag.	Ag = 28.4
Fraction III (a).	0.2780 of salt gave on ignition 0.0752 Ag.	Ag = 27.0
Fraction III (b).	0.3588 of salt gave on ignition 0.0978 Ag.	Ag = 27.3
Fraction III (c).	0.3017 of salt gave on ignition 0.0830 Ag.	Ag = 27.5
Fraction IV.	0.2442 of salt gave on ignition 0.0648 Ag.	Ag = 26.5

$C_{15}H_{20}O_8$ Ag requires Ag = 29.6 per cent.
$C_{17}H_{22}O_8$ Ag requires Ag = 27.5 per cent.

Ether Extract.—This was a dark red sirup. It was distilled under diminished pressure, when some decomposition occurred, and, although a portion of the distillate became solid, nothing definite could be isolated from it.

IV. *Ethyl Acetate Extract of the Resin.*

This extract, after the removal of the solvent, was a hard, friable, reddish brown mass, which could easily be reduced to a light brown powder.

Treatment with Dilute Alcoholic Sulphuric Acid.

One hundred grams of the dry extract were dissolved in alcohol, and some water added, together with such an amount of sulphuric acid that the latter represented about 5 per cent. of the weight of the mixture. The liquid, which amounted to 1.5 liters, was then heated in a reflux apparatus for about 5 hours, after which the alcohol was removed, water added, and steam passed through the mixture until volatile products ceased to pass over. The distillate, which contained some oily drops floating on the surface, was extracted with ether. The ethereal liquid was shaken with a solution of sodium carbonate, after which it was washed, dried, and the solvent removed. A very small amount of a yellowish oil was thus obtained, which gave a reaction for furfural. The sodium carbonate extract, when acidified and extracted with ether, yielded about 2 grams of a dark yellow, oily acid. This was distilled under the ordinary pressure, when it passed over for the most part between 174 and 178°.

0.1710 gave 0.3682 CO_2 and 0.1494 H_2O. C = 58.7; H = 9.7.
$C_5H_{10}O_2$ requires C = 58.8; H = 9.8 per cent.

An alcoholic solution of this acid was dextrorotatory, which confirmed its identity as *d*-methylethylacetic acid.

The above-mentioned, aqueous distillate, after extraction with ether, was found to contain formic and butyric acids.

After the removal of the volatile products of hydrolysis by distillation with steam, as above described, there remained in the distillation flask a dark red liquid, and a quantity of soft, resinous material which floated on the surface. The aqueous, acid liquid was separated from the resin, and extracted with ether, but this removed only a small amount of an oily product. It was finally treated with baryta from the removal of the sulphuric acid, filtered, and concentrated. A considerable quantity of a sirup was thus obtained, which readily yielded *d*-phenylglucosazone, melting at 206–207°. It was thus evident that at least a portion of the ethyl acetate extract of the resin was glucosidic.

The previously mentioned soft, resinous material, which had been separated from the above described, aqueous, acid liquid, was dissolved in alcohol, mixed with purified sawdust, and the thoroughly dried mixture extracted successively in a Soxhlet apparatus with light petroleum and ether.

Petroleum Extract.—This was a dark orange-colored sirup, which became partially solid on standing, and amounted to 10 grams. It was dissolved in ether, and the ethereal liquid shaken with a solution of sodium carbonate, after which the ether was dried and evaporated, when 2 grams of a dark yellow, oily liquid were obtained. The sodium carbonate extract was acidified and extracted with ether, the ethereal liquid being dried and the solvent removed. A quantity (4.7 grams) of an oily acid was thus obtained, which became solid on standing. The above-mentioned 2 grams of yellow, oily liquid were found to consist of an ester which had been formed by the treatment of the resinous material with alcoholic sulphuric acid. This was therefore hydrolyzed, and the acid thus obtained mixed with the 4.7 grams of acid previously obtained by extraction with sodium carbonate. The whole was then distilled under diminished pressure, when the greater portion passed over between 210 and 230°/12 mm., and formed a light yellow, soft solid. This was neutralized with potassium hydroxide, when a portion of the resulting potassium salt was observed to be sparingly soluble. The acid obtained from this sparingly soluble salt was dissolved in a mixture of light petroleum and ether, from which it separated in the form of a nearly colorless solid, melting at 47–48°.

0.1104 gave 0.2810 CO_2 and 0.1196 H_2O. C = 69.4; H = 12.0.
$C_{15}H_{30}O_3$ requires C = 69.8; H = 11.6 per cent.

This substance was thus identified as convolvulinolic acid, a further quantity of which was obtained from the alcohol extract of the resin.

The acid obtained from the more soluble portion of the above-described potassium salt was a soft, fat-like mass. From a portion of it three fractions of silver salt were prepared and analyzed.

I. 0.3118 of salt gave on ignition 0.0868 Ag. Ag = 27.8
II. 0.3014 of salt gave on ignition 0.0842 Ag. Ag = 27.9
III. 0.0626 of salt gave on ignition 0.0184 Ag. Ag = 29.4

$C_{16}H_{31}O_2$ Ag requires Ag = 29.6 per cent.
$C_{18}H_{35}O_2$ Ag requires Ag = 27.5 per cent.

These results would indicate that the above-described product consisted chiefly of a higher homologue of convolvulinolic acid, having the formula $C_{17}H_{34}O_3$. As previously noted, a similar product was obtained by the acid hydrolysis of the chloroform extract.

Ether Extract.—This was a soft, black, resinous mass, and amounted to 8 grams. It was examined, but nothing of a definite character could be obtained from it.

V. *Alcohol Extract of the Resin.*

This extract, as indicated in the first part of this paper, was the chief constituent of the original crude resin. When quite dry it could readily be reduced to a light brown powder, and on treating it in dilute alcoholic solution with successive portions of animal charcoal, a nearly white product was obtained. The latter, after drying at 110°, melted at 150–160°, and, when heated on platinum foil, it burned with a smoky flame, leaving no residue.

The optical rotatory power of the purified alcohol extract was determined, with the following result:

A solution containing 0.9905 gram of dry substance in 25 cc. of absolute alcohol had α_D —1.47° in a 1 dcm. tube, whence $[\alpha]_D$ —37.1°.

This value is almost precisely the same as that obtained for the purified total resin, namely $[\alpha]_D$ —37.0°, as recorded in the first part of the paper. It also agrees closely with the rotation ($[\alpha]_D$ —36.9°) observed by Kromer[1] for the product designated as "convolvulin," the latter consisting of that portion of jalap resin which is insoluble in ether.

Fusion with Potassium Hydroxide.

Twenty grams of the alcohol extract of the resin were fused with 120 grams of potassium hydroxide in a nickel basin, the temperature of the mixture being kept at about 150° for some time, after which it was slowly increased to 260°, with constant stirring. When the reaction had ceased, and the mass had become pasty, it was allowed to cool, and then dissolved in water. The solution was acidified with sulphuric acid, and distilled with steam until volatile products ceased to pass over. The distillate, which was found to contain only acidic substances, was made alkaline with sodium carbonate, the liquid concentrated, acidified, and extracted with ether, when a quantity of an oily acid was obtained. This was distilled twice under the ordinary pressure, and the following fractions finally collected: (1) Below 165°; (2) 165–175°; (3) 175–185°; (4) 185–245°; (5) 245–280°. Fractions (1), (2) and (3) were analyzed.

It would appear from these results that fraction (1) consisted of a nearly pure butyric acid, while fractions (2) and (3) evidently contained valeric acid. The subsequent fractions consisted of mixtures of acids of higher molecular weight.

---

[1] *J. Chem. Soc. Abst.*, 66, i, 540 (1894).

(1) 0.1940 gave 0.3870 CO_2 and 0.1586 H_2O. C = 54.4; H = 9.1
(2) 0.1732 gave 0.3660 CO_2 and 0.1478 H_2O. C = 57.6; H = 9.5
(3) 0.1862 gave 0.4124 CO_2 and 0.1652 H_2O. C = 60.4; H = 9.9
$C_4H_8O_2$ requires C = 54.5; H = 9.1 per cent.
$C_5H_{10}O_2$ requires C = 54.8; H = 9.8 per cent.
$C_6H_{12}O_2$ requires C = 62.1; H = 10.3 per cent.

The aqueous liquid from which the above-mentioned acids had been extracted by ether was distilled with steam, when the distillate was found to contain formic, acetic, and butyric acids.

After the removal of the volatile products of the potash fusion by distillation with steam, there remained in the distillation flask a yellow, aqueous liquid, which was completely extracted with ether. The ethereal liquid was washed, dried, and the solvent removed. A sirupy liquid was thus obtained, which, after standing for a few days, solidified to a crystalline mass. This was dissolved in water, the solution treated with animal charcoal and concentrated, when a product was obtained which, after further crystallization from water, separated in long, flat needles, melting at 110–111°. As the amount of this acid was small, it was converted into a silver salt, and the latter analyzed.

0.1918 of salt gave on ignition 0.1000 Ag. Ag = 52.1.
$C_{10}H_{16}O_4Ag_2$ requires Ag = 51.9 per cent.

The above-described substance was thus identified as sebacic acid, $C_{10}H_{18}O_4$, and its low melting point was evidently due to a slight impurity. This acid, as will be noted later, had been obtained by Hoehnel by the oxidation of convolvulinolic acid, $C_{14}H_{28}(OH)CO_2H$, but was regarded by him as an isomeride of sebacic acid, and therefore designated "ipomic acid."[1]

The mother liquor from the first crystallization of the sebacic acid was concentrated to a small bulk, when an acid separated in the form of laminae, which, after further crystallization, melted at 103–104°.

0.1082 gave 0.2274 CO_2 and 0.0862 H_2O. C = 57.3; H = 8.8.
$C_9H_{16}O_4$ requires C = 57.4; H = 8.5 per cent.

This substance was thus identified as azelaic acid, which had previously been obtained by the authors in a similar manner from the alcohol extract of the resin of *Ipomoea purpurea*, Roth.[2]

Hydrolysis of the Alcohol Extract of the Resin with Barium Hydroxide.

A quantity (200 grams) of the purified alcohol extract was dissolved in alcohol (1000 cc.), and a cold, saturated solution of barium hydroxide gradually added until the liquid showed an alkaline reaction. The liquid was then kept at a temperature of 35–40°, small portions of solution of barium hydroxide being added from time to time in order to maintain alkalinity. This treatment was continued until, on testing a small portion of the liquid with water, no turbidity was produced, a condition which was obtained in about 12 hours. The liquid was then allowed to cool, a little water added, and the alcohol removed, after which it was deprived of the excess of barium by means of carbon dioxide and filtering. The barium, which still remained in the filtrate in combination with the acids formed from the resin, was exactly precipitated with sulphuric acid, when, after removing the barium sulphate, a clear, dark red liquid was obtained. This liquid was subjected to distillation with steam in order to remove any volatile acids present. The distillate, which contained some oily drops floating on the surface, was made alkaline with sodium carbonate, concentrated, then acidified and extracted with ether, the ethereal liquid being washed, dried, and the solvent removed. A quantity (4 grams) of an oily product was thus obtained, which had the odor of valeric acid, and distilled between 174 and 176° as a colorless liquid.

---

[1] *Arch. Pharm.*, 234, 680 (1896).

[2] *Amer. J. Pharm.*, 80, 271 (1908).

0.1678 gave 0.3614 CO_2 and 0.1524 H_2O. C = 58.7; H = 10.1.
$C_5H_{10}O_2$ requires C = 58.8; H = 9.8 per cent.

The density of the acid was 0.9480 at 16.5°. It was optically active, and a determination of its specific rotatory power gave the following result:

α_D in a 25 mm. tube at 16° = +4° 10′, whence $[\alpha]_D$ +17.58°.

It was thus evident that the above-described liquid consisted of the optically active valeric acid (*d*-methylethylacetic acid, $CH(CH_3)(C_2H_5).CO_2H$), which is recorded[1] as having $[\alpha]_D$ +17.85°.

The liquid from which the valeric acid had been removed by extraction with ether was distilled with steam, when the distillate was found to contain small amounts of formic and butyric acids.

After the removal of the total volatile acids by distillation with steam, as above described, there remained in the distillation flask a clear liquid. This was extracted with ether, which, however, removed nothing. It was then concentrated under diminished pressure to the consistency of a sirup, when it still remained clear, and possessed a dark orange-yellow color. It had a strongly acid reaction, and did not reduce Fehling's solution until after heating with a mineral acid. For the further examination of this product, which may be termed the *hydrolyzed resin*, it was dissolved in alcohol, mixed with purified sawdust, and the thoroughly dried mixture extracted successively in a Soxhlet apparatus with the same solvents as had been employed for the extraction of the original mixture of resins. The results were as follows:

Petroleum (b. p. 40–60°) removed nothing.

---

[1] *Ber.*, 29, 52 (1896).

Ether and chloroform extracted 19.3 grams and 9 grams respectively of clear, orange-yellow sirups, which did not solidify.

Ethyl acetate extracted 54 grams of a dark, opaque sirup, which, when perfectly dry, could be reduced to a light brown powder. The latter was extremely hygroscopic, but if kept in a sealed tube, could be preserved unchanged.

Alcohol extracted 88 grams of a product, which formed a hard, brittle mass, and could be reduced to a nearly colorless powder.

Each of the above products from the hydrolyzed alcohol extract of the resin was then subjected to treatment with dilute sulphuric acid.

Ether Extract of the Hydrolyzed Resin.

The entire amount of this extract (19 3 grams) was dissolved in water, and such an amount of sulphuric acid added that the latter represented 5 per cent. by weight of the solution. The whole was then boiled in a reflux apparatus for about 6 hours, when a sirupy product separated which did not become solid on cooling, and the mixture was subsequently distilled with steam. The distillate, which contained a light yellow oil floating on the surface, was extracted with ether, and the ethereal liquid shaken with a solution of sodium carbonate. On evaporating the ether a very small amount of a neutral oil was obtained, which did not respond to the test for furfural and gave no color with ferric chloride. The sodium carbonate liquid was acidified and extracted with ether, the ethereal liquid being washed, dried, and the solvent removed, when 1.2 grams of a light yellow oil were obtained. This was unsaturated, since it absorbed bromine. It was distilled under diminished pressure, when the following two fractions were collected: (I) 120–140°; (II) 140–160°/15 mm., the latter distilling for the most part at about 160°/15 mm. The first fraction was analyzed with the following result:

I. 0.1480 gave 0.3534 CO_2 and 0.1362 H_2O. C = 65.1; H = 10.2.
$C_7H_{12}O_2$ requires C = 65.6; H = 9.4 per cent.

The remaining portion of this liquid yielded a fraction of silver salt which gave the following result on analysis:

0.1494 gave 0.2342 CO_2, 0.0796 H_2O, and 0.0590 Ag. C=42.7; H=5.9; Ag =39.5.
$C_{10}H_{17}O_2$ Ag requires C = 43.3; H = 6.1; Ag = 39.0 per cent.

Fraction I thus apparently consisted of a mixture of an acid $C_{10}H_{18}O_2$ with one of lower molecular weight.

II. 0.1560 gave 0.3978 CO_2 and 0.1516 H_2O. C = 69.5; H = 10.8.
$C_{10}H_{18}O_2$ requires C = 70.6; H = 10.6 per cent.

From the remainder of this fraction a silver salt was prepared and analyzed.

0.1270 gave 0.2000 CO_2, 0.0746 H_2O, and 0.0492 Ag. C=43.0; H=6.5; Ag=38.7.
$C_{10}H_{17}O_2$ Ag requires C = 43.3; H = 6.1; Ag = 39.0 per cent.

It will be seen from these results that fraction II agrees approximately in composition with a decylenic acid, $C_{10}H_{18}O_2$, but the amount of material available did not permit of its more complete examination. It was therefore impossible to ascertain whether the product was homogeneous.

Hoehnel,[1] by the treatment of so-called "purgic acid" with dilute sulphuric acid, obtained a product (b. p. 176°/135 mm.) which he regarded as decylenic acid, but this conclusion was based only upon the analysis of two amorphous salts and a determination of the iodine value. The latter figure, as found by Hoehnel (82.5), is, moreover, not in agreement with that required for decylenic acid, which is 146. It therefore cannot be considered as definitely established that decylenic acid has been obtained from jalap resin.

The aqueous distillate from which the oily acid had been obtained by extraction with ether was found to contain, furthermore, small amounts of formic and butyric acids.

After the removal of the volatile products by distillation with steam, as above described, there remained in the distillation flask a yellowish liquid, together with a viscid, oily product which floated on the surface. The mixture was extracted with ether, in which the oily product was completely soluble, and the ethereal solution then shaken with a solution of sodium carbonate. On subsequently evaporating the ether, only a very small amount of a neutral, oily liquid was obtained. The sodium carbonate liquid was acidified and extracted with ether, the ethereal liquid being washed, dried, and the solvent removed, when a quantity of a viscid, dark orange-colored product was obtained, which deposited nothing crystalline. When neutralized with a solution of sodium hydroxide, it formed a gelatinous mass, having the character of a soap The viscid, oily acid was distilled under diminished pressure, and the following fractions collected: (I) 192–194°; (II) 194–200°; (III) 200–210°; (IV) 210–220°; (V) 220–280°; (VI) 280–310°/15 mm. The total amount of these fractions was 12.2 grams. They were all viscid, yellow, unsaturated liquids, and on analysis gave the following results:

I 0.1492 gave 0.3520 CO_2 and 0.1398 H_2O. C = 64.3; H = 10.4
II. 0.1372 gave 0.3236 CO_2 and 0.1336 H_2O. C = 64.3; H = 10.8
III. 0.1778 gave 0.4202 CO_2 and 0.1714 H_2O. C = 64.5; H = 10.7
IV. 0.1152 gave 0.2770 CO_2 and 0.1126 H_2O. C = 65.7; H = 10.9
V. 0.1758 gave 0.4294 CO_2 and 0.1678 H_2O. C = 66.6; H = 10.6
VI. 0.1560 gave 0.3904 CO_2 and 0.1496 H_2O. C = 68.2; H = 10.6

The iodine absorption values of fractions I and VI were determined.

I. 0.3176 absorbed 0.0980 I. Iodine value = 30.9
VI. 0.3910 absorbed 0.1986 I. Iodine value = 50.8

---

[1] *Arch. Pharm.*, 234, 668 (1896).

It was evident from these results that the above fractions consisted of a mixture of acids, the identity of which could not be established.

The aqueous, acid liquid contained in the distillation flask, from which the above-described products had been removed by extraction with ether, was treated with baryta for the removal of the sulphuric acid. The filtered liquid was then concentrated under diminished pressure, when a small amount of a sirup was obtained which contained sugar, since it readily yielded *d*-phenylglucosazone, melting at 209–210°. This sirup also contained a small amount of a readily soluble, organic acid.

Chloroform Extract of the Hydrolyzed Resin.

This extract, which amounted to only 9 grams, was subjected to the same treatment with dilute sulphuric acid as has been described in connection with the ether extract of the hydrolyzed resin. On distilling the product with steam, a very small amount of an oily acid was obtained, together with formic and butyric acids. The contents of the distillation flask consisted of an aqueous, acid liquid, on the surface of which there was a small amount of a dark colored, viscid oil. The mixture was extracted with ether, which completely dissolved the oily product, the ethereal liquid being then shaken with a solution of sodium carbonate. On subsequently evaporating the ether, a very small amount of a neutral oil was obtained. The sodium carbonate liquid was acidified and extracted with ether, the ethereal liquid being washed, dried, and the solvent removed. A small amount of a dark orange-colored oil was thus obtained, from which no solid substance separated. It was therefore mixed with purified sawdust, and the mixture successively extracted with light petroleum and ether, but the resulting products were of an oily nature, and did not solidify. The acids were finally converted by fractional precipitation into a number of silver salts, the analysis of which, however, indicated them to consist of complex mixtures. The above-mentioned, aqueous liquid which had been extracted with ether was finally treated with baryta for the removal of the sulphuric acid, and filtered. It was then found to contain sugar, since it readily yielded *d*-phenylglucosazone, melting at 207–208°. It also contained a readily soluble, organic acid.

Ethyl Acetate Extract of the Hydrolyzed Resin.

This extract, which amounted to 54 grams, was obtained in the form of a dark, opaque sirup. As previously noted, it could be reduced to a powder after thorough drying, but the latter was extremely hygroscopic. It was heated for about 6 hours with dilute sulphuric acid, in the same manner as the two preceding extracts, and the product distilled with steam. The distillate, which contained some oily drops, was extracted with ether, and the ethereal liquid shaken with a solution of sodium carbonate. On subsequently evaporating the ether, only a very small amount of a neutral, oily liquid remained. The sodium carbonate liquid was then acidified and extracted with ether, the ethereal liquid being washed, dried, and the solvent removed. A quantity (5.2 grams) of an acid was thus obtained, which was distilled under the ordinary pressure, when it passed over for the most part between 174 and 178°.

0.1792 gave 0.3842 CO_2 and 0.1570 H_2O. $C = 58.5$; $H = 9.7$.
$C_5H_{10}O_2$ requires $C = 58.8$; $H = 9.8$ per cent.

The density of the acid was 0.9388 at 17.5°. A determination of its optical rotatory power gave the following result:

α_D in a 25 mm. tube at $17.5° = +4°7,'$ whence $[\alpha]_D + 17.53°$.

This acid was thus identified as the optically active valeric acid (*d*-methylethylacetic acid), $CH(CH_3)(C_2H_5).CO_2H$.

The distillate which had been extracted with ether was found to contain small amounts of formic and butyric acids.

After the removal of the volatile products by distillation with steam there remained in the distillation flask a dark colored liquid, together with a solid cake of resin, which was separated by filtration. The clear liquid was extracted with ether, but this removed only a small amount of oily substance, which did not permit of further examination. After extraction with ether the liquid was treated with baryta for the removal of the sulphuric acid, filtered, and the filtrate concentrated under diminished pressure. A sirup was thus obtained which contained sugar, since it yielded *d*-phenylglucosazone, melting at 207–208°. It also contained an organic acid which was readily soluble in water.

The above-mentioned, solid cake of resin, which was separated from the aqueous, acid liquid, was dissolved in alcohol, mixed with purified sawdust, and the mixture successively extracted with light petroleum, ether, and alcohol. The products from the first two solvents were of an oily nature, while the alcohol removed only a small amount of a hard resin. The petroleum and ether extracts were further examined, but they appeared to consist of a complex mixture of acids, of which no constituent could be definitely identified.

Alcohol Extract of the Hydrolyzed Resin.

This constituted the largest portion of the product of the alkaline hydrolysis of the resin. It formed a hard, transparent, light yellow mass, which could be reduced to a nearly colorless powder, and, unlike the ethyl acetate extract, was permanent in the air. It dissolved readily in water, yielding a clear solution, which was strongly acid to litmus. It melted at 110–115°, and with cold, concentrated sulphuric acid gave a deep red color. It was optically active, and a determination of its specific rotatory power gave the following result:

An aqueous solution containing 1.1060 grams of substance in 25 cc. had α_D —1° 29′ in a 1 dcm. tube, whence $[\alpha]_D$ —33.53°.

Hoehnel[1] has recorded for the so-called "convolvulic acid," to which he assigned the formula $C_{45}H_{80}O_{28}$, and which represented that portion of the product of the alkaline hydrolysis of "convolvulin" which was insoluble in ether and not volatile in steam, a specific rotatory power of —34.68°; whereas Kromer[2] had noted for a somewhat similar product $[\alpha]_D$ —31.33°.

For the examination of the above-mentioned extract 100 grams of material were employed. This was dissolved in water, and such an amount of sulphuric acid added that the latter represented 5 per cent. by weight of the mixture. The whole was then heated in a reflux apparatus for 4 hours, and the mixture allowed to cool, when it was observed that a resinous product had separated in the form of a soft, plastic mass. On passing steam through the mixture a slightly acid distillate was obtained, which contained no oily drops. It was made alkaline with sodium carbonate, concentrated, then acidified and extracted with ether, the ethereal liquid being washed, dried, and the solvent removed. A very small amount of an oily acid was thus obtained, which was converted into a silver salt, and the latter analyzed.

0.1396 of salt gave on ignition 0.0728 Ag. Ag = 52.1.
$C_5H_9O_2$ Ag requires Ag = 51.7 per cent.

This acid was thus identified as a valeric acid.

The acid liquid which had been extracted with ether was distilled with steam, when the distillate was found to contain small amounts of formic and butyric acids.

After the removal of the volatile products there remained in the distillation flask a dark colored liquid, which was decanted from the mass of resinous material and extracted with ether, but this removed only a small amount of a mixture of acids. The aqueous, acid liquid was finally treated with baryta for the removal of the sulphuric acid, and the filtered liquid concentrated under diminished pressure. A sirup was thus obtained which contained sugar, since it readily yielded *d*-phenylglucosazone, melting at 209–210°. It also contained a readily soluble organic acid.

The resinous material obtained by the above treatment, and which had been separated from the aqueous, acid liquid, was dissolved in alcohol, mixed with purified sawdust, and the thoroughly dried mixture extracted successively with light petroleum, ether, and alcohol.

Petroleum Extract.—This was a light yellow oil, which solidified to a fat-like mass, and amounted to 11.2 grams.

---

[1] *Arch. Pharm.*, 234, 662 (1896).

[2] *J. Chem. Soc. Abst.*, 66, i, 540 (1894).

Ether Extract.—This product was a soft, dark brown mass, and amounted to 9 grams.

Alcohol Extract.—This was a dark resinous mass, and amounted to only 4 grams. No crystalline substance could be obtained from it.

Isolation of Convolvulinolic Acid, $C_{14}H_{28}(OH).CO_2H$.
(*Hydroxypentadecylic Acid.*)

The above-mentioned petroleum extract, which was strongly acid to litmus, was mixed with water, and carefully neutralized with sodium hydroxide. The solution was then concentrated on a water bath, and, after filtering, was allowed to stand for some time, when a crystalline sodium salt separated. This was collected, dried on a porous plate, then dissolved in water, and the solution acidified with hydrochloric acid, when the organic acid separated in a solid state. It was collected on a filter, dried, and then crystallized three times from a mixture of light petroleum and ether, the solution being cooled in a freezing mixture of ice and salt. The acid then separated in the form of small, fine needles, which melted at 51–52°.

0.1288 gave 0.3284 CO_2 and 0.1416 H_2O. C = 69.5; H = 12.2.
$C_{15}H_{30}O_3$ requires C = 69.7; H = 11.6 per cent.

A portion of the acid was converted into a silver salt, and the latter analyzed.

0.1970 of salt gave on ignition 0.0580 Ag. Ag = 29.4.
$C_{15}H_{29}O_3$ Ag requires Ag = 29.6 per cent.

It is thus evident that the above-described acid possesses the formula $C_{15}H_{30}O_3$, and that it is identical with an acid of the same composition previously described by Taverne[1] as a hydroxypentadecylic acid (m. p. 50.5°) and by Hoehnel[2] as convolvulinolic acid (m. p. 51.5°). The latter designation appears, however, to have been given first by Mayer[3] and subsequently by Kromer,[4] to products obtained from jalap resin by methods analogous to that above described, but to which different formulas were assigned, and which were obviously not pure substances.

Methyl Convolvulinolate, $C_{14}H_{28}(OH).CO_2CH_3$.—One gram of convolvulinolic acid was dissolved in methyl alcohol, and the solution saturated with dry hydrogen chloride. After allowing the liquid to stand over night, it was poured into water, and the mixture extracted with ether, the ethereal liquid being washed with a dilute solution of sodium carbonate, then with water, dried, and the solvent removed. A light yellow, viscid product was thus obtained, which was distilled under diminished pressure, when it passed over as a colorless oil. On allowing the latter to stand, it solidified to a mass of small needles, which, after drying on a porous plate, melted at 32–33°.

---

[1] *Rec. trav. chim. Pays Bas,* **13,** 187 (1894); *J. Chem. Soc. Abst.,* **68,** i, 119 (1895).

[2] *Arch. Pharm.,* **234,** 674 (1896).

[3] *Ann.,* **83,** 121 (1852).

[4] *J. Chem. Soc. Abst.,* **66,** i, 540 (1894).

0.0940 gave 0.2420 CO_2 and 0.1012 H_2O. C = 70.2; H = 11.9.
$C_{16}H_{32}O_3$ requires C = 70.6; H = 11.8 per cent.

This substance was thus quite pure methyl convolvulinolate. It appears to have first been prepared by Taverne,[1] who has recorded its boiling point as 206–208°/15 mm., and its melting point as 35°.

Isolation of Ipurolic Acid, $C_{13}H_{25}(OH)_2.CO_2H$.

The above-mentioned ether extract, obtained from the product of the action of dilute sulphuric acid on the alcohol extract of the hydrolyzed resin, was a soft, dark brown mass. It was mixed with water, and carefully neutralized with sodium hydroxide. The solution was then concentrated on a water-bath, and allowed to cool, when a sodium salt separated in a partially crystalline condition. This salt was twice recrystallized from water, after which it was decomposed by hydrochloric acid, and the resulting acid extracted by means of ether. The solid thus obtained was twice recrystallized at a low temperature from a mixture of ether and chloroform, after which it melted at 94–95°. On subsequently crystallizing twice from the same mixture of solvents, and finally from chloroform, the melting point was raised to 100–101°.

0.1120 gave 0.2648 CO_2 and 0.1094 H_2O. C = 64.5; H = 10.8.
$C_{14}H_{28}O_4$ requires C = 64.6; H = 10.8 per cent.

A silver salt of the acid was also prepared and analyzed.

0.1496 of salt gave on ignition 0.0436 Ag. Ag = 29.1.
$C_{14}H_{27}O_4$ Ag requires Ag = 29.4 per cent.

The above-described substance was thus identified as ipurolic acid, $C_{13}H_{25}(OH)_2.CO_2H$, which was first isolated by the authors from the stems of *Ipomoea purpurea*, Roth.[2] When mixed with the acid obtained from the latter source, the melting point remained unchanged.

Methyl Ipurolate, $C_{13}H_{25}(OH)_2.CO_2CH_3$.—This was prepared by the method previously described.[3] When crystallized from dilute methyl alcohol it separated in fine, colorless needles, melting at 68–69°.

0.1070 gave 0.2562 CO_2 and 0.1056 H_2O. C = 65.3; H = 10.9.
$C_{15}H_{30}O_4$ requires C = 65.7; H = 10.9 per cent.

It may be noted in this connection that Hoehnel[4] has designated that portion of the product of the alkaline hydrolysis of "convolvulin" which is insoluble in ether as "convolvulic acid," and has assigned to it the formula $C_{45}H_{80}O_{28}$. He has furthermore assumed that the formation of convolvulinolic acid, $C_{15}H_{30}O_3$, from the last-mentioned product by its acid hydrolysis may be expressed by the following equation:

---

[1] *Loc. cit.*

[2] *Am. J. Pharm.*, 80, 273 (1908).

[3] *Loc. cit.*, p. 275.

[4] *Arch. Pharm.*, 234, 684 (1896).

$$C_{45}H_{80}O_{28} + 5H_2O = 5C_6H_{12}O_6 + C_{15}H_{30}O_3.$$

It has been shown, however, by this investigation that the portion of the product of the alkaline hydrolysis of the resin which was not only insoluble in ether, but which had also been deprived of constituents soluble in chloroform and ethyl acetate, when submitted to the action of dilute sulphuric acid, yielded, besides sugar and convolvulinolic acid, a number of other acids, among which formic, butyric, valeric, and ipurolic acids were identified. A portion of the product, moreover, is apparently not glucosidic, and remains after the treatment with sulphuric acid in the form of an organic acid which is readily soluble in water. It is obvious, therefore, that the formation of all these substances can not be expressed by a simple equation, and that the amorphous product designated as "convolvulic acid" can by no means be regarded as an individual substance, which is capable of being represented by a chemical formula.

Oxidation of the Alcohol Extract of the Hydrolyzed Resin with Nitric Acid.

Ten grams of the previously described alcohol extract of the hydrolyzed resin were dissolved in a little water, and about 100 grams of nitric acid (sp. gr. 1.4) added. A vigorous reaction soon ensued, and when this had subsided the mixture was heated for a time, after which water was added, and the heating continued for about 10 minutes. On allowing the liquid to cool, a quantity of substance was deposited, which was extracted with ether, and the ethereal liquid then shaken with a solution of sodium carbonate. The ether was subsequently dried and evaporated, when only a slight oily residue was obtained. The sodium carbonate liquid was acidified and extracted with ether, the ethereal liquid being dried and the solvent removed, when 1.4 grams of an oily product were obtained, which soon solidified to a perfectly white, crystalline mass. This was repeatedly crystallized from water, when two principal fractions were obtained, melting at 105–106° and 122–125° respectively. The final mother liquor contained a small amount of an acid which was freely soluble in water, and was evidently oxalic acid.

The fraction melting at 105–106° consisted of long, flat needles, and was analyzed with the following result:

0.1072 gave 0.2266 CO_2 and 0.0844 H_2O. C = 57.6; H = 8.7.
$C_9H_{16}O_4$ requires C = 57.4; H = 8.5 per cent.

This substance was thus identified as azelaic acid, the melting point of which has been recorded as 106°.

The fraction melting at 122–125° was obtained in the form of small needles, and gave on analysis the following result:

0.0768 gave 0.1676 CO_2 and 0.0658 H_2O. C = 59.5; H = 9.5.
$C_{10}H_{18}O_4$ requires C = 59.4; H = 8.9 per cent.

This substance was evidently sebacic acid, the melting point of which has been variously stated as 127–128° and 133–133.5°.

By the oxidation of convolvulinolic acid with potassium permanganate, as also with nitric acid, Hoehnel[1] obtained, besides a valeric acid, a crystalline, dicarboxylic acid of the composition $C_{10}H_{18}O_4$ (m. p. 109°), which he has designated as ipomic acid ("ipomsäure"), and regards it as isomeric with sebacic acid. The name of *ipomic* or *ipomoeic* acid was first given by Mayer[2] to a product obtained by the action of nitric acid on that portion of jalap resin which is insoluble in ether, and which he designated "convolvulin." The acid obtained by Mayer was stated to agree with the formula $C_5H_9O_2$, and to melt at 104°. Neison and Bayne,[3] who repeated the experiment of Mayer, have shown, however, that the so-called ipomoeic acid is identical with sebacic acid, for by the oxidation of material designated by them as "jalapin" they obtained an acid melting at 126–127°, and agreeing in all respects with sebacic acid, the melting point of which they record as 127–128°. This fact appears not to have been considered by Hoehnel,[4] who has retained the name of "ipomsäure" for a substance which was evidently somewhat impure sebacic acid. The present investigation has shown, moreover, that the sebacic acid obtained as above described is accompanied by a lower homologue, namely, azelaic acid. A mixture of these two acids was likewise obtained, as already noted, from the product of the fusion of the alcohol extract of the resin with potassium hydroxide.

Summary.

In view of the extended experimental details of this investigation, a summary of the more important results may here be given.

The material employed consisted of an original bale of jalap tubers of good quality. On completely extracting the jalap with hot alcohol, and subjecting the resulting extract to distillation with steam, a small amount of an *essential oil* was obtained. This oil was at first of a pale yellow color, but became very dark on standing. The odor was smoky and disagreeable. It distilled between 80 and 160°/60 mm., had a density of 0.8868 at 20°/20°, and was optically inactive.

The portion of the extract which was soluble in water contained chiefly coloring matter and sugar, the latter yielding *d*-phenylglucosazone

[4] *Loc. cit.*

(m. p. 217–218°). The portion of the extract insoluble in water represents the product known as "resin of jalap," which is recognized by most of the national Pharmacopoeias. The amount of this resin contained in the drug, as indicated by a special assay of the latter, corresponded to 9.4 per cent. of its weight, and 11.6 per cent. of it was soluble in ether. The total crude resin, when purified by means of animal charcoal, had a specific optical rotation of —37.0°. On extracting the crude resin successively with (I) light petroleum (b. p. 40–60°), (II) ether, (III) chloroform, (IV) ethyl acetate, and (V) alcohol, a number of products were obtained, the examination of which has shown the resin to be of much more complex composition than has previously been assumed.

I. *Petroleum Extract of the Resin.*—This represented 1.9 per cent. of the total resin. It contained palmitic and stearic acids in a free state, and, after hydrolysis, yielded formic, butyric and higher volatile acids, palmitic acid, and a mixture of unsaturated acids, which appeared to consist chiefly of linolic acid. From the unsaponifiable portion of the extract there were obtained a phytosterol, $C_{27}H_{46}O$ (m. p. 134–135°; $[\alpha]_D$ —32.4°), cetyl alcohol, $C_{16}H_{34}O$, and a small amount of a substance melting at 56–57°, which agrees in composition with the formula $C_{18}H_{38}O$. This *substance*, which appears to be a new compound, yields color reactions similar to those of the phytosterols.

II. *Ether Extract of the Resin.*—This represented 9.7 per cent. of the total resin. From it there was isolated a small amount of a new, dihydric alcohol, which possesses the formula $C_{21}H_{32}O_2(OH)_2$, and is designated *ipurganol*. Ipurganol crystallizes in colorless needles, melting at 222–225°, and has, in pyridine solution, $[\alpha]_D$ —44.9°. It yields color reactions similar to those given by the phytosterols. *Diacetylipurganol*, $C_{21}H_{32}O_4(CH_3.CO)_2$, forms colorless leaflets, melting at 166–167°, and has, in pyridine solution, $[\alpha]_D$ —36.0°. The ether extract, after treatment with alkalis and dilute sulphuric acid, yielded, furthermore, a little phytosterol and cetyl alcohol, small amounts of volatile acids, and a quantity of amorphous products.

III. *Chloroform Extract of the Resin.*—This represented 24.1 per cent. of the total resin. From it there was isolated a very small amount of β-methylaesculetin, $C_9H_5(CH_3)O_4$. After treatment with alkalis and dilute sulphuric acid this extract yielded, furthermore, formic, butyric, and *d*-methylethylacetic acids, together with convolvulinolic acid, $C_{15}H_{30}O_3$, and apparently a higher homologue of the latter. Glucose was also produced by this treatment, thus indicating that a portion of the extract was of a glucosidic nature.

IV. *Ethyl Acetate Extract of the Resin.*—This represented 22 per cent. of the total resin. On treatment with dilute alcoholic sulphuric acid, it yielded formic, butyric, and *d*-methylethylacetic acids, together with convolvulinolic acid, $C_{15}H_{30}O_3$, and apparently a higher homologue of the latter, having the composition $C_{17}H_{34}O_3$. It also yielded, besides indefinite amorphous products, a considerable quantity of a sugar, which was evidence that at least a portion of the extract was of a glucosidic nature.

V. *Alcohol Extract of the Resin.*—This represented 38.8 per cent. of the total resin. After treatment with animal charcoal it was obtained in the form of a nearly white powder, which melted at 150–160°, and had $[\alpha]_D$ —37.1°. When fused with potassium hydroxide it yielded formic, acetic, butyric, valeric, and higher volatile acids, together with azelaic and sebacic acids. When subjected to alkaline hydrolysis with baryta it yielded, besides small amounts of formic and butyric acids, *d*-methylethylacetic acid, $C_5H_{10}O_2$ (b. p. 174–176°; $[\alpha]_D$ +17.55°), together with a quantity of an amorphous product, readily soluble in water, which may be designated as the hydrolyzed resin. This has now been shown to be of very complex composition, for by successive extraction with (*a*) ether, (*b*) chloroform, (*c*) ethyl acetate, and (*d*) alcohol it is capable of being resolved into a number of products.

(*a*) *Ether Extract of the Hydrolyzed Resin.*—This extract, on heating with dilute sulphuric acid, yielded formic, butyric, and other acids, together with sugar.

(*b*) *Chloroform Extract of the Hydrolyzed Resin.*—This extract, like the preceding one, yielded small amounts of formic, butyric, and other acids, together with sugar.

(*c*) *Ethyl Acetate Extract of the Hydrolyzed Resin.*—This extract, on heating with dilute sulphuric acid, yielded formic, butyric, *d*-methylethylacetic, and other acids, together with sugar.

(*d*) *Alcohol Extract of the Hydrolyzed Resin.*—This extract could be obtained in the form of a nearly colorless powder, which melted at 110–115°, and had $[\alpha]_D$ —33.53°. When heated with dilute sulphuric acid it yielded, in addition to sugar, small amounts of formic, butyric, and valeric acids, together with convolvulinolic and ipurolic acids. The last-mentioned acid possesses the formula $C_{13}H_{25}(OH)_2.CO_2H$, and was first obtained by the authors from the stems of *Ipomoea purpurea*, Roth.[1] By the oxidation of this extract with nitric acid, azelaic and sebacic acids were obtained.

Each of the above-described extracts of the hydrolyzed resin appeared to be only partly glucosidic, and to contain a readily soluble organic acid which was unaffected by the treatment with dilute sulphuric acid.

Physiological Tests.

The extracts obtained by the treatment of the original jalap resin with various solvents, as above described, were kindly tested for us with respect to their physiological action by Dr. H. H. Dale, Director of the Wellcome Physiological Research Laboratories, and our thanks are due to him for the assistance rendered in this connection.

---

[1] *Am. J. Pharm.*, 80, 273 (1908).

One gram of each of the extracts was administered to dogs, with the following results:

1. The petroleum extract had no effect.
2. The ether extract produced prompt, but not severe purgation.
3. The chloroform extract caused repeated purgation, lasting for 48 hours.
4. The ethyl acetate extract was similar in its action to the chloroform extract, the purgation lasting 24 hours.
5. The alcohol extract produced repeated and powerful purgation.

Apart from the purgative action of the various extracts no effect was observed, all the animals having remained perfectly well. It was furthermore concluded by Dr. Dale that the apparent differences in the degree of action of the extracts II, III, IV, and V cannot be regarded as of great importance in view of individual differences with respect to the action of drugs, and of purgatives in particular.

The product resulting from the alkaline hydrolysis of the alcohol extract of the resin, consisting of acids readily soluble in water, had no effect when administered to a dog in doses of 1 gram. This result is in accordance with the observations previously recorded respecting an analogous but less completely purified product from jalap resin, which has been designated "convolvulic acid."[1]

Conclusions.

In considering the results of this investigation, some of the more important facts and deductions may specially be noted.

In the first place, it has been shown that the resin of jalap is of much more complex composition than has hitherto been assumed, and that none of the amorphous products obtained from it possess the attributes of a homogeneous substance. It follows that the formulas which have heretofore been assigned to products such as the so-called convolvulin, purgic acid, convolvulic acid, etc., are devoid of any significance or scientific value, and they should therefore no longer be retained in chemical literature. The same considerations will doubtless apply to the various amorphous products obtained from other convolvulaceous resins to which distinctive names and formulas have been assigned.

In the present investigation of jalap resin, as already indicated, a number of substances have been obtained which permitted of definite identification or characterization. It is evident, however, that the formation of these substances, when resulting from the degradation of an amorphous product of the resin, can by no means be expressed by simple chemical equations.

---

[1] Compare Husemann, "Die Pflanzenstoffe," 2nd edit., 1882, p. 1141.

It may finally be observed that the purgative action of jalap resin is not due to any single or well-defined constituent, inasmuch as the products obtained by its successive extraction with various solvents, with the exception of the portion removed by light petroleum, appear to possess about an equal degree of physiological activity.

ACTION OF AMINES ON PHTHALIC ACID. VI.[1]

By J. Bishop Tingle and B F. Parlett Brenton.

Received November 2, 1909.

In the course of the work described in our earlier paper, we studied the interaction of phthalic anhydride on a number of amino derivatives other than those we have already mentioned. The products which we ultimately obtained did not prove to be suitable for our intramolecular rearrangement investigations and consequently we did not carry on the work with them very far. We desire, however, to record the results which we have obtained, because we cannot continue our experiments conjointly.

Camphylamine and phthalic anhydride, when melted together, gave what is probably the *imide*,  $C_6H_4\left\langle\begin{matrix}CO\\CO\end{matrix}\right\rangle NC_{10}H_7$, m. 54°. No solid hydrolysis product (amidic acid) could be obtained from it.

Benzidine and phthalic anhydride, under similar conditions, yielded a highly insoluble compound of great stability.

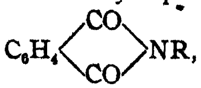
We made a large number of experiments with the object of "fixing" the mobile amidic hydrogen atom in the amidic acids, $RNHCOC_6H_4CO_2H$. With phosphorus pentachloride, phosphorus trichloride, or thionyl chloride, the only stable product of the reaction was the imide  $C_6H_4\left\langle\begin{matrix}CO\\CO\end{matrix}\right\rangle NR$. We then directed our attention to the preparation of acylated amidic acids, such as $CH_3CONRCOC_6H_4CO_2H$. We attempted to prepare them by the action of acyl chlorides and of acid anhydrides on the amidic acids and also from acyl amines and phthalic anhydride. We found, however, that acetyl chloride or acetic anhydride either failed to react with the amidic acids, or else it transformed them into the imide, behaving in this respect exactly like the phosphorus halides mentioned above. Most of our experiments were made with phthalphenylamidic acid. Our attempts at synthesis were carried out with phthalic anhydride and acetanilide, *p*-acetotoluidide and formo-β-naphthalide, respectively. When fractionally recrystallized, the products gave fairly sharp melting points, but further investigation showed that we were dealing with mixtures and that the phthalic anhydride, so far as it reacts at all, simply displaces the acetyl or formyl group from the amine, phthal-β-naphthylimide, for example, being produced from the above formo-β-naphthalide.

---

[1] The previous papers bearing on this subject have appeared as follows: Bishop Tingle and Cram, *Am. Chem. J.*, 37, 596 (1907); Bishop Tingle and Lovelace, *Ibid.*, 38, 642 (1907); Bishop Tingle and Rolker, This Journal, 30, 1882 (1908); Bishop Tingle and Brenton, *Ibid.*, 31, 1157 (1909); Bishop Tingle and Bates, 31, 1233 (1909).

We failed to obtain any crystalline compound from 2,4-diaminophenol and phthalic anhydride, but from *m*-aminobenzoic acid we prepared the dicarboxylic acid, $HO_2\overset{1}{C}C_6H_4\overset{3}{N}HCO\overset{1}{C}_6H_4\overset{2}{C}O_2H$.[1]

The interaction of carbamide and of certain of its alkyl derivatives with phthalic anhydride has been studied previously.[2] When the mixture of the two compounds is heated in a test tube it melts, becomes solid as the temperature is raised and finally liquefies again. During the heating gas is evolved almost continuously, but chiefly towards the later stages of the experiment. The gas consists of ammonia and carbon dioxide, or in the case of a thiocarbamide, of carbon oxysulphide. The solid product of the reaction is a phthalimide,



$C_6H_4\langle{}^{CO}_{CO}\rangle NR$, in a fairly pure condition. After being once recrystallized it shows the correct melting point. This method of preparing the compounds in question is so easy and requires so little time that it is obviously the best to employ for the preparation, in relatively small quantity, of the imides in which $R = H$, CH_3, C_2H_5, or some other group, the amino or halide derivative of which is very volatile. We experimented with carbamide and its methyl, ethyl, benzyl and phenyl derivatives, and also with phenylthiocarbamide, obtaining phthalimide, and phthalmethyl-, ethyl-, benzyl- and phenylimides, respectively. Ethylidene carbamide gave only a tar. In the course of our experiments with phenylcarbamide we were successful in isolating phthalphenylamidic acid, $C_6H_5NHCO C_6H_4CO_2H$, as an intermediate product. Its formation throws some light on the mechanism of the reaction. To accomplish this was one of the chief objects of our investigation.

We have made some experiments, of a preliminary nature, on the action of aniline and 4,5-dichlorophthalic acid. The results show that the substances react in a more complicated manner than in the case of aniline and phthalic acid.

Experimental.

1. *Camphylamine and Phthalic Anhydride.*—When these substances

---

[1] Gabriel. Puitti, *Ber.*, 16, 1320.

[2] Piutti, *Ann.*, 214, 20. Dunlap, *Am. Chem. J.*, 18, 337.

are fused together, in molecular proportion, water is evolved. The product appears to be *phthalcamphylimide*,  $C_6H_4\langle{CO \atop CO}\rangle NC_{10}H_7$; after being recrystallized from benzene it melts at 54°.

N found, 5.67; calculated, 4.94 per cent.

The substance was warmed with an aqueous solution of sodium carbonate and the clear solution acidified; this caused the deposition of an oil.

2. *Benzidine and Phthalic Anhydride.*—When melted together these substances combine. The resulting compound is very sparingly soluble in all the ordinary media. It was dissolved in nitrobenzene and precipitated by benzene, but we are uncertain as to its purity because it remained unmelted at 300°. Our specimen contained 7.37 per cent. of nitrogen. It failed to react with benzoyl chloride, by the Schotten-Baumann method. In a similar experiment, employing 2 mols. of base : 1 mol. of anhydride, the product appeared to be similar to that obtained in the first experiment, or identical with it.

3. *Acetanilide, p-Acetotoluidide, Formo-β-Naphthalide and Phthalic Anhydride.*—As explained in the theoretical part of this paper, our experiments with these substances were carried out in the hope of preparing disubstituted phthalamidic acids, $RR'NCOC_6H_4CO_2H$, in which one of the groups, R or R', could be easily removed. The acylated bases were melted with the anhydride, and the heating continued during varying periods ranging from a few minutes to 1.5 hours. The resulting materials, after recrystallization, usually melted within 1°, but, in each case, further purification caused the melting point to vary widely from that shown at first and the analytical results were not constant. From formo-β-naphthalide we were able to isolate and identify phthal-β-naphthylimide and to prove that formic acid was evolved during the heating. It is evident, therefore, that the phthalyl group merely replaces the acyl already linked to the nitrogen of the amine.

4. *2,4-Diaminophenol and Phthalic Anhydride.*—A considerable number of experiments were carried out with these substances, but no definite compound could be isolated.

5. *m-Aminobenzoic Acid and Phthalic Anhydride.*—We prepared the dicarboxylic acid, $HO_2\overset{1}{C}C_6H_4\overset{3}{N}H\overset{1}{C}OC_6H_4\overset{2}{C}O_2H$, in the manner described above and purified it by means of its sodium salt from the strongly colored materials which are produced during its formation. It dissolved readily in ethyl alcohol (40 per cent.), but the deposited material failed to exhibit crystalline structure. It was recovered unchanged by boiling with acetic anhydride and also by treatment with benzoyl chloride, by the Schotten-Baumann method.

6. *Carbamide and Phthalic Anhydride.*—When these substances are mixed in equimolecular proportion and heated they melt, then after a time solidify and, finally, as the temperature is raised, become liquid again. During the heating ammonia and carbon dioxide are evolved vigorously. The product consists of phthalimide,  $C_6H_4\left\langle\begin{matrix}CO\\CO\end{matrix}\right\rangle NH$; it was fully identified by its melting point and analytical results. The same substance was obtained by the use of 2 molecular proportions of carbamide, under otherwise similar conditions. The yield was almost quantitative.

7. *Methylcarbamide and Phthalic Anhydride.*—These substances, when treated in the same manner as the carbamide, behaved similarly, giving phthalmethylimide,  $C_6H_4\left\langle\begin{matrix}CO\\CO\end{matrix}\right\rangle NCH_3$ (m. p. 132°), carbon dioxide and ammonia. The yield was almost quantitative.

8. *Ethylcarbamide and Phthalic Anhydride.*—The product in this case was phthalethylimide. The yield was relatively small.

9. *Benzylcarbamide and Phthalic Anhydride.*—These substances reacted like the methylcarbamide, the product being phthalbenzylimide,  $C_6H_4\left\langle\begin{matrix}CO\\CO\end{matrix}\right\rangle NCH_2C_6H_5$. The yield was good. An unsuccessful attempt was made to isolate the intermediate compound, the formation of which is indicated by the molten mass becoming solid. The only materials which could be identified were the mother-substances.

10. *Phenylcarbamide and Phthalic Anhydride.*—When these substances are melted together and the heating stopped as soon as they solidify, the product consists of phthalphenylamidic acid, $C_6H_5NHCOC_6H_4CO_2H$, which was fully identified. In another experiment the heating was continued until all reaction had ceased. In this case the only substance which was obtained was phthalphenylimide.

11. *Phenylthiocarbamide and Phthalic Anhydride.*—These substances behaved exactly like the phenylcarbamide mixture, except that the gases which were evolved were ammonia and carbon oxysulphide.

12. *Ethylidenecarbamide and Phthalic Anhydride.*—The product from this experiment was tarry.

The results recorded above show that the preparation of phthalimide and its alkyl derivatives is carried out far more easily by means of the carbamides than by the use of the amines, or from the alkyl halides and potassium phthalimide, provided that only relatively small quantities of material are required (5–10 grams) and that the amine or alkyl derivative is so volatile as to require the use of a sealed tube or autoclave.

13. *Aniline and 4,5-Dichlorophthalic Acid.*—A number of preliminary experiments have been made with these compounds. The results show that the conditions require much more careful regulation than in the case of phthalic acid.

Summary.

1. We have studied the action of phthalic anhydride on a number of amines, including camphylamine, which gives the camphylimide; benzidine, which forms an insoluble product; and *m*-aminobenzoic acid, which yields a dicarboxylic acid.
2. The acylated amines, acetanilide, *p*-acetotoluidide and formo-β-naphthalide, eliminate the acyl group when heated with phthalic anhydride.
3. Carbamide and certain alkyl- and arylcarbamides, including phenylthiocarbamide, eliminate ammonia and carbon dioxide (or carbon oxysulphide) and form phthalimides or phthalamidic acids.

It is intended to continue the investigation of the interaction of phthalic acids and amines in this laboratory during the coming year.

McMaster University, Toronto, Canada.

NOTE ON THE OXIDATION OF β-NAPHTHOQUINONE.

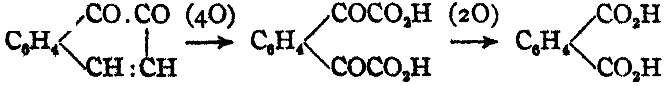
By C. H. Robinson.

Received November 1, 1909

In a series of experiments on the oxidation of naphthalene and various naphthalene derivatives, Daly[1] found some indications that in the oxidation of β-naphthoquinone by potassium permanganate in alkaline solution the reaction ceased before the amount of permanganate had been reduced which would correspond to the oxidation of the naphthoquinone to phthalonic acid and he mentions the possibility of the diketo acid, $C_6H_4(COCO_2H)_2$, being formed in the solution. Under the direction of Professor Allan, the author investigated this reaction in the hope of preparing the diketo acid in this way.

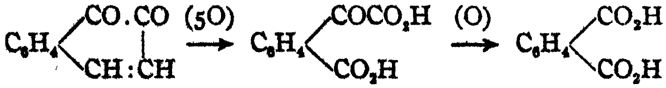
If the oxidation in alkaline solution were to the diketo acid and then in acid solution to phthalic acid the two stages of the reaction might be represented by A, but if the oxidation in alkaline solution were to phthalonic acid they would be represented by B.

A.



$$C_6H_4\left\langle\begin{matrix}CO.CO\\ |\quad\ |\\ CH:CH\end{matrix}\right. \xrightarrow{(4O)} C_6H_4\left\langle\begin{matrix}COCO_2H\\ \\ COCO_2H\end{matrix}\right. \xrightarrow{(2O)} C_6H_4\left\langle\begin{matrix}CO_2H\\ \\ CO_2H\end{matrix}\right.$$

B.



$$C_6H_4\left\langle\begin{matrix}CO.CO\\ |\quad\ |\\ CH:CH\end{matrix}\right. \xrightarrow{(5O)} C_6H_4\left\langle\begin{matrix}COCO_2H\\ \\ CO_2H\end{matrix}\right. \xrightarrow{(O)} C_6H_4\left\langle\begin{matrix}CO_2H\\ \\ CO_2H\end{matrix}\right.$$

---

[1] *J. Phys. Chem.*, 11, 105.

So that the ratio of the amounts of oxygen used in the two stages of the reaction would be two according to A or five according to B.

The β-naphthoquinone was prepared by the method of Lagodzinski and Hardine[1] and purified by the method given by Boswell.[2] It is slightly soluble in decinormal sodium bicarbonate solution (0.54 g. per liter) and not more soluble in a normal solution.

To find the ratio between the amount of permanganate required to oxidize the naphthoquinone in alkaline solution and the permanganate required to complete the oxidation in acid solution to phthalic acid, 110 cc. of a saturated solution of the quinone in decinormal sodium bicarbonate was added to 50 cc. decinormal permanganate solution and left at laboratory temperature for twenty-four hours. In 50 cc. of this solution the residual permanganate was determined by adding a solution of 0.4 g. potassium iodide and 2 g. sulphuric acid in 100 cc. water and titrating the iodine set free. To another 50 cc. of the solution two per cent. sulphuric acid and a few drops of manganese sulphate solution were added, and after two minutes, by which time the oxidation to phthalic acid was complete, the solution of potassium iodide and sulphuric acid was added and the iodine determined. Since the oxidizing power of the permanganate is 1.66 times greater in acid solution than in alkaline solution, the permanganate used in oxidizing the solution to phthalic acid was multiplied by 1.66 so that the amounts of permanganate would be in proportion to their oxidizing value.

	I.	II.
$\frac{\text{Permanganate reduced in alkaline solution}}{\text{Permanganate reduced in acid solution}}$	4.65	4.75

This shows conclusively that the oxidation is as represented above in B and that the reaction in alkaline solution proceeds to phthalonic acid, but it is still possible that there is a rapid oxidation to the diketo acid and then a slower oxidation to phthalonic acid.

Some experiments were made to determine the constituents of the solution at various stages of the oxidation by adding small amounts of permanganate to the quinone solution, allowing the reaction to proceed till all the permanganate was reduced, acidifying the solution and ethering out. As the residual quinone is so much more insoluble in water than the products of the reaction, the residue obtained by the evaporation of the ether contained little else than quinone.

A = initial weight of quinone in the solution.
B = cc. permanganate used to 50 cc. quinone solution.
C = weight of residue from ether.
D = weight of quinone which would be left if oxidation were direct to phthalonic acid.

---

[1] *Ber.*, 27, 3075.

[2] This Journal, 29, 230.

E = weight of quinone which would be left if oxidation were to diketo acid.

A. Gram.	B. cc.	C. Gram.	D. Gram.	E. Gram.
0.0226	1	0.0209	0.0210	0.0206
0.0226	6	0.0126	0.0131	0.0108
0.0226	8	0.0110	0.0100	0.0068
0.0226	10	0.0087	0.0069	0.0023

The results given in this table are not very good because the method was inaccurate but they confirm the conclusion arrived at from the previous experiments that there is no intermediate stage in the oxidation of β-naphthoquinone to phthalonic acid in alkaline solution. A series of experiments, in which the rate of oxidation of the quinone in alkaline solution was determined, also gave no indication of the existence of an intermediate product.

Further experiments to prepare the diketo acid by the saponification of phthalyl cyanide are now being carried out.

RESEARCHES ON QUINAZOLINES (TWENTY-FOURTH PAPER). ON OXALYL ANTHRANILIC COMPOUNDS AND QUINAZOLINES DERIVED THEREFROM.[1]

BY MARSTON TAYLOR BOGERT AND ROSS AIKEN GORTNER.

Received November 27, 1909.

In 1883, Kretschy[2] obtained by oxidation of kynurine, or of kynurenic acid, an acid which he called "kynuric acid." The succeeding year[3] he showed that this "kynuric acid" was oxalyl anthranilic acid.

The following pages describe various derivatives of oxalyl anthranilic acid and condensation products obtained therefrom.

Mauthner and Suida[4] have recorded the fact that when anthranilic acid is heated with ethyl oxalate, both oxalyl dianthranilic acid and ethoxalyl anthranilic acid are produced:

$$\mathrm{HOOC.C_6H_4.NH_2 + ROOC.COOR = HOOC.C_6H_4.NHCOCOOR + ROH,}$$

$$\mathrm{2HOOC.C_6H_4.NH_2 + ROOC.COOR =}$$
$$\mathrm{HOOC.C_6H_4.NHCOCONH.C_6H_4.COOH + 2ROH,}$$

and we have used this method for the preparation of these substances, as well as for the methoxalyl anthranilic acid. Oxalyl dianthranilic acid was also prepared by the action of oxalyl chloride upon anthranilic acid.

---

[1] Read at the meeting of the New York Section, March 5, 1909.

[2] *Monatsh. Chem.*, 4, 157 (1883).

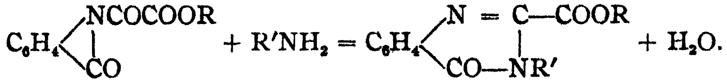
[3] *Ibid.*, 5, 30 (1884).

[4] *Monatsh. Chem.*, 9, 743 (1888).

By the action of acetic anhydride, these acyl anthranils were changed to acyl anthranils,

$$\overline{\text{OC.C}_6\text{H}_4\text{.N}}\text{COCOOR and } \overline{\text{OC.C}_6\text{H}_4\text{.N}}\text{COCO}\overline{\text{N.C}_6\text{H}_4\text{.CO}},$$

which were then treated with various primary amines to get the corresponding quinazolines:[1]



$$\text{C}_6\text{H}_4\left<\begin{matrix}\text{NCOCOOR}\\ |\\ \text{CO}\end{matrix}\right. + \text{R'NH}_2 = \text{C}_6\text{H}_4\left<\begin{matrix}\text{N} = \text{C—COOR}\\ \quad\quad |\\ \text{CO—NR'}\end{matrix}\right. + \text{H}_2\text{O}.$$

The reactions with the methoxalyl and ethoxalyl anthranils resulted in the formation of the expected quinazolines, the amines used being ammonia, methylamine, aniline, β-naphthylamine, hydrazine and phenylhydrazine.

Some of the results are, however, rather puzzling. Thus, when ethoxalyl anthranil was heated with alcoholic ammonia, the product was the ammonium salt of the quinazoline acid, $\overline{\text{HN.CO.C}_6\text{H}_4\text{.N} = \text{C}}\text{.COONH}_4$; but when the anthranil was fused with urea, or boiled with an alcoholic solution of urea, the quinazoline ester was obtained, $\overline{\text{HN.CO.C}_6\text{H}_4\text{.N} = \text{C}}$.COOR.

Ethoxalyl anthranil, heated with an alcoholic solution of methylamine, gave the quinazoline amide, $\text{CH}_3\overline{\text{N.CO.C}_6\text{H}_4\text{N} = \text{C}}\text{.CONHCH}_3$, and hydrazine similarly gave a hydrazide. Aniline, β-naphthylamine, and phenylhydrazine, on the other hand, did not displace the ester group, but gave quinazoline esters, even when the reaction was pushed to the point where a second molecule of the amine condensed with the keto group of the quinazoline to an anil, $\text{C}_6\text{H}_5\text{N.C(:NC}_6\text{H}_5\text{).C}_6\text{H}_4\text{.N} = \text{C.COOR}$.

Experimental.

Methoxalyl Anthranilic Acid, $(1)\text{HOOC.C}_6\text{H}_4\text{.NHCOCOOCH}_3(2)$.—An equimolecular mixture of anthranilic acid and methyl oxalate was heated at 140–55°. The mixture melted, methyl alcohol distilled off, and after 30 minutes' heating a hard cake remained. This was pulverized fine, washed with cold water and the residue repeatedly extracted with dilute alcohol. From the alcoholic extracts, combined and concentrated, crystals were obtained which on recrystallization from water melted at 176.5° (corr.). For analysis, they were further purified by recrystallization from a mixture of alcohol and benzene, washed with ligroin, and dried at 110°.

[1] Anschütz, Schmidt and Greiffenberg, *Ber.*, 35, 3480 (1902). Bogert and Chambers, THIS JOURNAL, 27, 649 (1905). Bogert and Seil, *Ibid.*, 27, 1305 (1905). Bogert and Steiner, *Ibid.*, 27, 1327 (1905), *et al.*

Calculated for $C_{10}H_9O_5N$: N, 6.27.
Found: N, 6.17.

The acid dissolves readily in cold sodium carbonate solution with evolution of carbon dioxide. It is also soluble in hot water, alcohol, or benzene; difficultly soluble in cold water, practically insoluble in chloroform or ligroin.

In this preparation, some oxalyl dianthranilic acid is also formed.

Ethoxalyl Anthranilic Acid, (1)$HOOC.C_6H_4.NHCOCOOC_2H_5$(2).—Mauthner and Suida[1] have already reported on the formation of this compound from anthranilic acid and ethyl oxalate. It was, however, first obtained by von Baeyer[2] by oxidizing ethyl indoxylate with sulphuric acid and potassium dichromate. von Baeyer gives its melting-point as 180–1°.

Twenty grams anthranilic acid were mixed with slightly more than an equimolecular amount of ethyl oxalate and the mixture heated for an hour at 140–50°, followed by ten minutes further heating at 160°. When cold, the melt was pulverized and extracted with boiling water. From the hot aqueous extract, colorless needles of ethoxalyl anthranilic acid separated on cooling, melting sharply at 184° (corr.). Yield, 27 grams. From the residue insoluble in water, 1.4 grams oxalyl dianthranilic acid were isolated.

Oxalyl Dianthranilic Acid (*Oxanilide Di-o-carbonic Acid*), (1)$HOOC.C_6H_4.NHCOCONH.C_6H_4.COOH$(2).—That this acid is formed by heating together anthranilic acid and ethyl oxalate has already been noted by Mauthner and Suida.[1]

We prepared it by heating 1 molecule of methyl or ethyl oxalate with 2 molecules of anthranilic acid for half an hour to an hour at 140–155°, removing methoxalyl- or ethoxalyl anthranilic acid by extracting the crude product with boiling water and dilute alcohol. We also prepared it by dissolving anthranilic acid in dry benzene and adding oxalyl chloride. The reaction was violent, with evolution of copious fumes of hydrochloric acid, and the precipitate was purified by washing (digestion) with benzene and with alcohol.

The purified products obtained by the above methods were identical. The substance is a white powder, decomposing at about 330° (uncorr.), and is insoluble in the ordinary neutral organic solvents. When freshly prepared from methyl oxalate, it seems to be appreciably soluble in alcohol, but on standing becomes practically insoluble in it.

Methoxalyl Anthranil, $\overline{OC.C_6H_4.N}.COCOOCH_3$.—Methoxalyl anthranilic acid was boiled for several minutes with excess of acetic anhydride and the solution then concentrated to crystals. These crystals were pressed dry on a porous plate and recrystallized from dry benzene. They then melted sharply at 177.5° (corr.). As the methoxalyl anthranilic acid has a melting point very close to this (176.5° corr.), it was thought at first that we had only recovered the original substance unaltered, but on mixing with some of the methoxalyl anthranilic acid, the melting point was lowered to 150° (uncorr.). The pure dry substance gave the following figures on analysis:

---

[1] *Loc. cit.*

[2] *Ber.*, 15, 777 (1882).

Calculated for $C_{10}H_7O_4N$: N, 6.83.
Found: N, 7.02.

This anthranil crystallizes from dry benzene or acetic anhydride in pale brownish needles. It is very sensitive to moisture, being hydrolyzed to methoxalyl anthranilic acid by ordinary commercial absolute alcohol (99.8 per cent.) or by ordinary glacial acetic acid.

Ethoxalyl Anthranil, (1)$OC.C_6H_4.N.COCOOC_2H_5$, was prepared in similar manner from the ethoxalyl anthranilic acid and acetic anhydride. Recrystallized from acetic anhydride, it forms large, colorless plates, melting at 129–130° (corr.). Yield, 81 per cent. of the theoretical.

Calculated for $C_{11}H_9O_4N$: N, 6.40.
Found: N, 6.67.

In contrast with the above methyl derivative, this ethoxalyl anthranil is not very easily hydrolyzed. It may even be recrystallized from relatively dilute alcohol without suffering any extensive hydrolysis. Boiling water rapidly hydrolyzes it to the ethoxalyl anthranilic acid again.

Oxalyl Dianthranil, $OC.C_6H_4.N.COCON.C_6H_4.CO$. — Five grams oxalyl anthranilic acid were boiled for three hours with excess of acetic anhydride, the solid changing from white to yellow. The insoluble material was filtered out and washed with acetic anhydride. Yield, 3.4 grams. For analysis, this crude product was boiled again for three hours with acetic anhydride, washed with the anhydride, and dried at 110°.

Calculated for $C_{16}H_8O_4N_2$: C, 65.75; H, 2.74; N, 9.59.
Found: C, 65.20, 64.97, 65.81; H, 3.20, 2.87, 3.05; N, 9.98.

The purified oxalyl dianthranil is a yellow powder, melting with decomposition at about 345° (uncorr.), and is insoluble in the ordinary neutral solvents. Boiling water slowly hydrolyzes it to anthranilic and oxalic acids. It is readily hydrolyzed by hot concentrated hydrochloric acid.

4-Quinazolone-2-carboxylic Acid (4-Hydroxyquinazoline-2-carboxylic Acid), $HN.CO.C_6H_4.N = C.COOH \rightleftarrows N = C(OH).C_6H_4.N = C.COOH$.

Ammonium Salt, $C_8H_5ON_2.COONH_4$.—Two grams ethoxalyl anthranil were added to a slight excess of ammonia dissolved in 95 per cent. alcohol. The anthranil dissolved with evolution of heat and a white precipitate suddenly separated. The mixture was heated to 100°, the precipitate filtered out and washed repeatedly with 95 per cent. alcohol. Yield of this ammonium salt, nearly theoretical.

Calculated for $C_9H_9O_3N_3$: N, 20.28.
Found: N, 20.26.

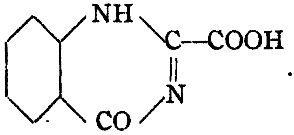
The ammonium salt crystallizes from water in long silky colorless needles, melting at 229° (corr.) with evolution of ammonia and carbon dioxide.

Free Acid.—Cold concentrated hydrochloric acid was added to the ammonium salt and then water. The free acid separated in a gelatinous condition and was crystallized from dilute alcohol. White silky needles resulted, softening at 227° and melting with evolution of carbon dioxide at 230° (corr.). The melt on cooling congealed in colorless needles, and re-melted at 214° (corr.). The melting point of 4-quinazolone (4-hydroxyquinazoline) as found by different investigators is variously stated from 209 to 216.5°.

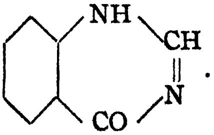
Calculated for $C_9H_6O_3N_2$: N, 14 73.
Found: N, 14.97.

The acid is easily soluble in hot alcohol, only slightly soluble in benzene, and very difficultly soluble in water. Boiled with mineral acids, it gradually loses carbon dioxide.

In 1885, Griess[1] described a compound which he called "carboxylcyanamidobenzoyl," and to which he assigned the formula



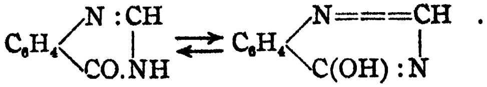
When this acid was heated, Griess found that it lost carbon dioxide giving another substance, which he named "carbimidamidobenzoyl" and formulated thus



Subsequent investigations of Weddige,[2] Knape,[3] Bischler and Burkart,[4]

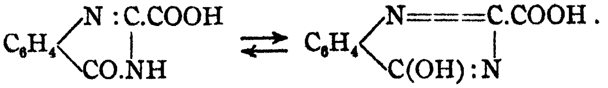
[1] *Ber.*, 18, 2418 (1885).
[2] *J. prakt. Chem.*, [2] 31, 124 (1885).
[3] *Ibid.*, 43, 227 (1891).
[4] *Ber.*, 26, 1349 (1893).

Niementovski,[1] and Bogert and Hand[2] showed that this "carbimidamidobenzoyl" was the simple 4-quinazolone and should be formulated



$$C_6H_4\left\langle\begin{matrix}N:CH\\ |\\ CO.NH\end{matrix}\right. \rightleftarrows C_6H_4\left\langle\begin{matrix}N{=\!=\!=}CH\\ |\\ C(OH):N\end{matrix}\right. .$$

From this it follows that the formula for "carboxylcyanamidobenzoyl" should be written



$$C_6H_4\left\langle\begin{matrix}N:C.COOH\\ |\\ CO.NH\end{matrix}\right. \rightleftarrows C_6H_4\left\langle\begin{matrix}N{=\!=\!=}C.COOH\\ |\\ C(OH):N\end{matrix}\right. .$$

Reissert and Grube[3] have recently obtained this same acid by the rearrangement in dilute acid solution of *o*-cyanoxanilic acid, $NC.C_6H_4.NHCOCOOH$.

Griess describes his acid as crystallizing in leaflets, but gives no melting point. Reissert and Grube, like ourselves, obtained the acid in needles. They give a melting point of 201–202°. We do not understand how they found so low a melting point, unless they did not recrystallize their product sufficiently. It does not appear from the article that they recrystallized their compound to constant melting point.

Ethyl Ester, $C_8H_5ON_2.COOC_2H_5$.—1.5 grams ethoxalyl anthranil and 0.42 gram urea were melted together at 125°. The temperature was then raised slowly to 140–150° and kept there for an hour. The cold melt was extracted with alcohol, and from the alcoholic extracts on cooling a crystalline material separated which was filtered out, washed with water and dried. The same substance was obtained when ethoxalyl anthranil (1 gram) and urea (0.33 gram) were boiled together in alcohol solution. For analysis, the compound was recrystallized from alcohol and dried at 110°.

Calculated for $C_{1}H_{10}O_3N_2$: N, 12.83.
Found: N, 12.90.

It crystallizes from alcohol in minute colorless needles, melting at 185.5° (corr.), and is insoluble in water or in mineral acids. It dissolves easily in solutions of the caustic alkalies, but not in strong sodium carbonate solution. Heated with aqueous ammonia, the ammonium salt of the acid (described above) results, apparently without any amide. That alcohol is split off by the action of alkalies was shown by the iodoform test.

3-Methyl-4-quinazolone-2-carbomethylamide, $CH_3N.CO.C_6H_4.N = C.CONHCH_3$.—One molecule of ethoxalyl anthranil was added to an aqueous solution of slightly more than 2 molecules methylamine, and the solution concentrated to small bulk. On standing several days, beautiful pale-rose prisms separated, melting sharply at 160° (corr.). They were dried at 110° and analyzed:

[1] *J. prakt. Chem.*, [2] 51, 564 (1895).

[2] This Journal, 24, 1048 (1902).

[3] *Ber.*, 42, 3713 and 3715 (1909).

Calculated for $C_{11}H_{11}O_2N_3$: N, 19.35.
Found: N, 19.51.

The compound is very soluble in water; much less soluble in alcohol.

Methyl 3-Phenyl-4-quinazolone-2-carboxylate, $C_6H_5N.CO.C_6H_4.N = C.COOCH_3$.—0.5 gram methoxalyl anthranil was mixed with a slight excess of aniline and the mixture heated carefully with the naked flame. As soon as the boiling commenced, the flame was removed and the action allowed to continue without further heating. Water was evolved and, on cooling, the mixture solidified. It was extracted with dilute alcohol, and from this extract small colorless plates separated on cooling, m. p. 203.5° (corr.) with previous softening in the neighborhood of about 120° (uncorr.). The yield was very poor. For analysis, the compound was recrystallized from dilute alcohol and dried at 110°.

Calculated for $C_{16}H_{12}O_3N_2$: N, 10.0.
Found: N, 9.78.

The ester is easily soluble in alcohol, but very slightly soluble in water. Heated with excess of aniline, it gives a difficultly soluble compound, probably similar to the anil described beyond.

Ethyl 3-Phenyl-4-quinazolone-2-carboxylate, $C_{14}H_9ON_2.COOC_2H_5$.—0.5 gram ethoxalyl anthranil was heated for a few minutes with excess of aniline, and the mass then cooled and extracted with 95 per cent. alcohol. Colorless plates separated from the alcoholic extract on cooling.

Calculated for $C_{17}H_{14}O_3N_2$: N, 9.50.
Found: N, 9.40.

This ester melts at 160° (corr.). It is but slightly soluble in water, easily soluble in alcohol. In cold potassium hydroxide solution, it is apparently insoluble, but dissolves on warming. It is not hydrolyzed readily by hot concentrated hydrochloric acid.

Ethyl 3-Phenyl-4-phenyliminoquinazoline-2-carboxylate,

$C_6H_5N.C(:NC_6H_5).C_6H_4.N = C.COOC_2H_5$.—This anil is obtained simultaneously with the above ester from the interaction of ethoxalyl anthranil and excess of aniline. If the heating is continued many minutes, the yield of anil is good. It can be separated easily from the keto ester by its insolubility in alcohol. For analysis, it was washed repeatedly with hot alcohol and dried at 110°.

Calculated for $C_{23}H_{19}O_2N_3$: N, 11.36.
Found: N, 11.40.

It is a colorless crystalline powder, insoluble in water and in all the ordinary neutral organic solvents. It melts with effervescence at 291° (corr.).

Ethyl 3-β-Naphthyl-4-β-naphthyliminoquinazoline-2-carboxylate,

$C_{10}H_7N.C(: NC_{10}H_7).C_6H_4.N = C.COOC_2H_5$.—0.5 gram ethoxalyl anthranil and 0.5 gram β-naphthylamine were carefully melted together, and the temperature then gradually raised to the boiling point. The melt was allowed to cool, and was then thoroughly extracted with 95 per cent. alcohol. The insoluble residue was dried at 110° and analyzed.

Calculated for $C_{31}H_{23}O_2N_3$: N, 8.95.
Found: N, 8.83.

It is a grayish crystalline powder, insoluble in water, ethyl or amyl alcohol, acetone or benzene, and melts to an amber liquid at 253–4° (corr.).

Ethyl 3-Anilino-4-quinazolone-2-carboxylate, $C_6H_5NHN.CO.C_6H_4.N = C.COOC_2H_5$.—An equimolecular mixture of ethoxalyl anthranilic acid and phenylhydrazine was heated to boiling. Water was evolved, but there was no evidence of any alcohol being given off. On cooling, a clear amber glass resulted. This was crystallized from alcohol, and the crystals obtained washed with dilute alcohol. Recrystallized from alcohol, long lemon-yellow needles were obtained, melting at 142° (corr.).

Calculated for $C_{17}H_{15}O_3N_3$: N, 13.58.
Found: N, 13.65.

The compound is insoluble in water, but dissolves readily in alcohol, benzene or acetone, giving bright yellow solutions. It is insoluble in cold solutions of caustic alkalies, but dissolves on heating. It does not dissolve in dilute mineral acids.

Sym. Di-(3-amino-4-quinazolone-2-carboxylic Acid) Hydrazide,

$H_2NN.CO.C_6H_4.N = C.CONHNHCO.C = N.C_6H_4.CO.NNH_2$.—One gram of hydrazine hydrate (in 50 per cent. aqueous solution) was diluted with 95 per cent. alcohol, 2 grams ethoxalyl anthranil gradually stirred in, and the mixture heated to boiling. The undissolved substance turned light yellow. It was filtered out and the yellow filtrate on standing deposited an additional amount of this same yellow amorphous material. It is slightly soluble in the ordinary neutral organic solvents, and melts at 157–158° (corr.) with loss of ammonia, thereby becoming insoluble and infusible. Yield, 2.1 grams. For analysis, it was recrystallized from a large volume of absolute alcohol, and dried at 110°.

Calculated for $C_{18}H_{14}O_4N_6$: N, 27.60.
Found: N, 27.91.

Treated with acetic anhydride, a thick sirup resulted which defied all attempts to crystallize or purify it.

The same hydrazide was produced when methoxalyl anthranil was used instead of the ethoxalyl compound. Varying the proportions of anthranil and hydrazine did not appear to affect the result.

2-Carbazino-3-amino-4-quinazolone, $H_2N\overline{N.CO.C_6H_4.N = C}.CONHNH_2$, was obtained from its hydrochloride (see below) by dissolving the latter in water, adding potassium hydroxide solution to alkalinity and then acidifying with acetic acid. The precipitated free base was washed with water and crystallized from dilute alcohol acidified with acetic acid. Beautiful transparent plates were obtained, carrying water of crystallization. This water of crystallization was driven out at 100–110°, and the crystals then became opaque and melted at 202.5° (corr.).

Calculated for $C_9H_8O_2N_5$: N, 31.96.
Found: N, 31.70.

The substance is appreciably soluble in water and easily soluble in alcohol. When once dissolved, it does not separate again readily, and the loss on recrystallization is therefore considerable. A small amount tends to precipitate in an amorphous state.

Hydrochloride, $C_9H_8O_2N_5.3HCl$.—One gram ethoxalyl anthranil was added to an aqueous solution of half a gram hydrazine hydrate diluted with 95 per cent. alcohol, and the mixture heated to boiling. The above *sym.* diquinazolone hydrazide (m. 157–158°) separated. Without removing the latter, concentrated hydrochloric acid was poured in and the mixture again boiled. The colorless hydrochloride which separated was washed with 95 per cent. alcohol. Yield, 0.8 gram. For analysis, it was recrystallized from a mixture of dilute hydrochloric acid and alcohol, washed with alcohol, and dried at 110°.

Calculated for $C_9H_8O_2N_5.3HCl$: N, 21.43.
Found: N, 21.97.

It is freely soluble in water, but insoluble in most of the ordinary organic solvents, and melts at 190–191° (corr.). From strong hydrochloric acid, it crystallizes in colorless needles. As this monohydrazide is presumably formed by the hydrolysis of the dihydrazide which first separated, there should be produced simultaneously the 3-amino-4-quinazolone-2-carboxylic acid, but we have been unable to isolate any such compound from the mother liquors.

Acetyl Derivative, $CH_3CONH\overline{N.CO.C_6H_4.N = C}.CONHNHCOCH_3$.—0.8 gram 2-carbazino-3-amino-4-quinazolone hydrochloride and 0.6 gram fused sodium acetate were added to an excess of acetic anhydride and the solution boiled down to small bulk. More acetic anhydride was then added, the precipitated salt (NaCl) filtered out, and the filtrate boiled down twice more with acetic anhydride, finally carrying the evaporation to dryness. The residual clear amber glass was dissolved in 95 per cent. alcohol, the solution concentrated and benzene added. The acetyl derivative separated in a fine yellowish powder, and was washed thoroughly with benzene and dried. Yield, 0.35 gram.

Calculated for $C_{13}H_{13}O_4N_5$: N, 23.10.
Found: N, 23.16.

The pure substance melts at 125° (corr.). It is easily soluble in water, alcohol or chloroform, but does not crystallize well from these solvents, evaporation of the solvent leaving finally a clear glass. On long boiling with benzene, small transparent plates were obtained, carrying benzene of crystallization.

Attempts to eliminate water from this compound and condense the side chains to a cycle proved unsuccessful.

NEW YORK, N. Y.

PREPARATION OF CHOLINE AND SOME OF ITS SALTS.

By R. R. RENSHAW.

Received November 22, 1909.

In connection with some work on the bactericidal properties of lecithins the author had occasion to prepare some of the salts of choline. In looking through the literature it was found that the choline used in recent investigations was prepared and isolated by methods which it was thought might be simplified.

Wurtz in 1867[1] prepared choline by heating trimethylamine with an excess of ethylene chlorohydrin, and later (1868) he and also Griess and Harrow[2] (1885) obtained it by the action of a concentrated solution of trimethylamine on ethylene oxide. The products were purified by means of the gold salt.

Later investigators have used different procedures or new methods. In 1889 Bode[3] made choline by the prolonged action of dilute nitric acid on bromomethyltrimethylamine bromide which he had made from ethylene bromide by Hofmann's method. No yield was given. Gulewitsch in 1898[4] in an extended article on choline described its preparation in quantity by a modification of Wurtz's method. Redistilled anhydrous ethylene chlorohydrin in large excess was heated with a 15–20 per cent. solution of trimethylamine in absolute alcohol for 24 hours in a water bath. The choline from the resulting slightly acid solution was separated partly as the mercuric, and partly as the platinic chloride double salts. Yield, 61 per cent. Krüger and Bergell in 1903[5] got choline by the action of water on bromocholine bromide at 160° for 4 hours. No yield given. A large number of investigators have prepared choline from egg lecithin. For the most part these later methods are either tedious or give poor yields or both.

The author has found that a practically quantitative yield (97.3 per cent.) of choline chloride can be obtained by the following method. Fourteen grams of freshly distilled anhydrous ethylene chlorohydrin were placed in a bomb tube cooled to —12 to —20° (saturated salt solution and snow). Trimethylamine, generated by dropping a concentrated solution of its hydrochloride (18 grams) on solid sodium hydroxide, was passed through a U-tube containing solid potassium hydroxide and then through a freezing bath into the ethylene chlorohydrin contained in the bomb tube. If the amine hydrochloride was added slowly, practically complete condensation ensued. After all the hydrochloride had been added the generating flask was warmed gently and air passed through slowly. The tube was then sealed and heated two hours at 80–90° when the contents had completely crystallized. On opening the tube after a further two hours' heating there was a little pressure due to a slight excess of trimethylamine. The contents, composed of perfectly white, well-formed crystals, were washed a number of times with dry ether, and allowed to stand for some time in a vacuum desiccator. The product so obtained, while sufficiently pure for most purposes, still contained too high a percentage of chlorine—probably due to a slight amount of ethylene chlorohydrin held mechanically in or on the crystals. A pure product was obtained by dissolving in absolute alcohol and adding ether gradually until complete precipitation was obtained. The fine white needle crystals were filtered, washed with ether, and dried in a vacuum.

Choline Acetate was prepared by neutralizing an aqueous solution of the base (obtained by the action of moist silver oxide on choline chloride) with acetic acid. Very long evaporation under high vacuum at 50° and cooling caused the product to crystallize to a fan-shaped mass of needle crystals. These were extremely hydroscopic, and practically insoluble in carbon disulphide, benzene, petroleum ether, acetone and ethyl ether; very soluble in alcohol and water. Choline acetate is very easily hydrolyzed.

Choline Sulphate, $(HOCH_2CH_2N(CH_3)_3)_2(SO_4)$, prepared by the action of silver sulphate on choline chloride, separates from a very concentrated aqueous solution in short needles. The salt was purified by evaporating to dryness under high vacuum at 50–100° (almost no decomposition occurred), dissolving in alcohol, filtering, adding petroleum ether and refrigerating. Perfectly white well-formed needle crystals separated out. These were practically insoluble in carbon disulphide, ether, benzene and petroleum ether; easily soluble in alcohol and water. The sulphate is fairly hydroscopic.

Calculated for $(HOCH_2CH_2N(CH_3)_3)_2SO_4$: S, 10.52 per cent.
Found: S, 10.63, 10.77 per cent.

Choline Dihydrogen Phosphate, $HOCH_2CH_2N(CH_3)_3H_2PO_4$.—On agitating a concentrated solution of choline chloride with silver phosphate and filtering from the excess of silver phosphate and silver chloride, a very basic solution was obtained, indicating that the tricholine phosphate was largely hydrolyzed. A dilute solution of phosphoric acid was added to permanent acidity. The ratio of phosphate ions to the choline was then practically 1 : 1. The solution was evaporated under high vacuum at 80–90° to a horny mass. The product was purified by extracting with boiling absolute alcohol in which the phosphate is slightly soluble. By this means beautiful, long white, fairly hydroscopic needle crystals were obtained, which were practicably insoluble in benzene, carbon disulphide, petroleum ether, acetone and ethyl ether; slightly soluble in alcohol; very soluble in water. After washing in ether and drying in a vacuum desiccator the product was analyzed.

Calculated for $HOCH_2CH_2N(CH_3)_3H_2PO_4$: P, 15.42 per cent.
Found: P, 15.48 per cent.

The chemistry of the choline derivatives is being further investigated by the author.

BACTERICIDAL PROPERTIES OF LECITHINS AND CHOLINE SALTS.

BY R. R. RENSHAW AND K. N. ATKINS.

Received November 22, 1909.

There is some disagreement in the literature concerning the bactericidal properties of lecithins. The existence of cobra lecithides, the speculation regarding a possible relation between lecithin and the amboceptors,[1] and, among others, the fact that such a product as fresh milk, containing certain amounts of lecithins, has some germicidal constituent, gives interest to the problem in question. In view of this the authors have attempted to determine what influence, if any, lecithins might have upon the growth of some of the more common organisms. Along with this, since it is possible that the presence of a decomposition product, *i. e.*, choline, might have been responsible for the disagreement, a few of its salts were prepared and their bactericidal properties determined.

The procedure was as follows: Pure cultures of the different organisms were grown at room temperature for about twelve hours in an ordinary broth medium. One loopful of this was transferred to a flask containing about 50 cc. of the same kind of medium. After a thorough shaking this second broth culture was divided among small bottles holding 9 cc. of the medium. In the experiments on milk the raw fresh product was used. To the different bottles of the culture or milk 1 cc. of a 4 per cent. emulsion of lecithin or 4 per cent. solutions of the different choline salts were added. One bottle was used as a control. After the organisms had developed 12 hours, 1 cc. of the medium was withdrawn from each bottle by means of a sterile pipette and transferred to sterile water blanks of either 9 or 99 cc., making a dilution of 10 or 100. The water blanks were then thoroughly shaken and if higher dilutions were to be used, as was true in most cases, 1 cc. of the diluted culture was transferred to a second water blank and again thoroughly shaken. In this way the proper dilution was reached. Anticipating from other experiments the approximate number of bacteria which would develop under given conditions the dilution was so calculated as to allow accurate counting of the plates. Knowing that the number of bacteria in milk kept for 24 hours at 19° would be large (in fact the product was almost sour) the dilution here used was as high as 1,000.000. In all cases 1 cc. of this finally diluted culture was plated out in agar, incubated for 24–48 hours at 37° and counted. The agar medium used contained 1.2 per cent. agar-agar and its acidity was equivalent to 1 per cent. normal acid.

[1] Kyes, *Z. physiol. Chem.*, 41, 273.

Commercially pure samples of lecithins were repurified by several precipitations from alcoholic solutions by means of acetone and subsequent drying in a vacuum desiccator. The concentration of the emulsions was low, about 0.4 per cent. This, however, is greater than is usually found in biological fluids.

With some of the organisms, especially typhoid, a large number of series were made. The following tables are composed of representative determinations. The figures in each are the average counts of ten to a dozen plates.

In several series the organisms were plated out after incubating 6 or 24 hours. It was found, however, that a twelve-hour period was the best.

As indicated in the tables, there is, in general, a varying retardation in the development of bacteria in the cultures containing lecithins, although this is not marked in some cases. In fact, in looking over the records of individual plates, it was found that in about 10 per cent. of over two hundred plates no change at all was shown, or there was a very slight increase in the development. Nevertheless, we are inclined to attribute slight bactericidal properties to lecithins at these dilutions, although for practical purposes this is negligible.

In general an effect by choline salts was less frequently observed and with them the diminution was less marked.

FURTHER STUDIES ON THE APPLICATION OF THE VOLHARD METHOD TO THE ESTIMATION OF ALKALOIDS.

BY ELIAS ELVOVE.

Received November 15, 1909.

It has been pointed out by the writer[1] that the difficulty experienced by many workers in obtaining suitable indicators in the alkalimetric estimation of alkaloids and the necessity for using a comparatively large number of such indicators, each more or less suitable to one or only a few alkaloids, may be completely overcome if we adopt the very simple modification of the usual procedure and substitute hydrochloric acid as the solvent for the alkaloid instead of sulphuric acid which is usually employed.[1] That is, instead of dissolving the isolated free alkaloid in a measured excess of sulphuric acid and determining the excess of acid with the aid of the indicator best suitable for that particular alkaloid, the latter is dissolved in an excess of hydrochloric acid and the excess of acid got rid of by simple evaporation on the water bath, thus obtaining a salt of the alkaloid which, as long pointed out by Plugge[2] and others, may in many cases be estimated with the aid of phenolphthalein as indicator and hence indirectly also the amount of alkaloid. Further, that by thus converting the alkaloids into their hydrochlorides it becomes possible to estimate the alkaloids indirectly through a determination of the chlorine by the beautiful and exact Volhard method. In this way, in addition to avoiding the necessity for using a comparatively large number of different indicators, each more or less suitable to one or only a few alkaloids, we are supplied with a means for estimating such alkaloids as do not react very sharply with any of the indicators thus far studied. Thus of the eleven different indicators which Kippenbeger studied,[3] namely, lacmoid, iodeosine, uranin, cochineal, azolitmin, haematoxylin, methyl orange, ethyl orange, phenolphthalein, alkannin, and Congo red, the only ones which he found to lend themselves in any way for use in the titration of quinine were azolitmin and haematoxylin. The applicability, however, of azolitmin to quinine titrations is denied by Rammstedt;[4] while the misleading results obtainable when haematoxylin is used as indicator in titrating cinchona alkaloids may be seen from the results obtained by Hille,[5] who states that under circumstances which should require 1.3 cc. of 0.1 *N* acid, one may be in doubt as to the end reaction to the extent of making an error equivalent to a whole cubic centimeter of the 0.1 *N* solution, which would make the error about 77 per cent. It is probably owing to this apparent lack of a suitable indicator in titrating cinchona alkaloids that the U. S. Pharmacopoeia (1905), at present official, recommends a gravimetric process in all assays[1] where these alkaloids are involved, although it is a recognized fact[2] that the alkaloidal residues obtained in the course of assay frequently contain considerable neutral non-alkaloidal matter, and hence, probably on this account, titration with standard acid is recommended in the cases of most of the other pharmacopoeial alkaloidal assays. Finally, it was pointed out[3] that such procedure applied to the alkaloids would also conclusively show the exact relative acidity of the various alkaloids and the apparent uncertainty[4] as to the exact relative acid-combining power of such alkaloids as quinine and strychnine, for example, would be entirely cleared up.

[5] *Arch. Pharm.*, 241, 106 (1903). Hille expresses himself in this connection as follows: "Da angenommen wird, das 50 g. genau $^2/_3$ der Chloroform-Aether-Flüssigkeit ist, sollen zur Bindung der Alkaloide 1,3 cm. Säure verbraucht sein. Der Endpunkt der Titration ist nun aber bei Anwendung von Haematoxylin als Indicator sehr schwierig zu erkennen. Ich habe viele Dutzend Titrationen mit Haematoxylin als Indicator auszuführen versucht. Es ist niemals mit Sicherheit zu sagen: Jetzt ist der Farbenumschlag eingetreten. Man wird im allgemeinen bei Anwendung von 1/10 Normallösungen innerhalb eines ganzen Kubikzentimeters im Zweifel sein, ob der Farbenumschlag eingetreten ist oder nicht. Nimmt man jedoch den Punkt als richtig an, wo eben die Flüssigkeit anfängt, die Farbe etwas zu verändern, so bekommt man viel zu niedrige Resultate, wie ich mit reinen Alkaloiden nachgewiesen habe. Von dieser ersten Farbenänderung an ändert sich mit jedem Tropfen 1/10 Normal-Kalilauge die Färbung etwas, so dass man immer im Zweifel ist, wann der richtige Punkt eingetreten ist. Titrationen welche ich mit reinen Alkaloiden ausführte, ergaben Resultate von 85–115 per cent. der angewandten Menge."

Recently, Poirrier blue has been recommended by Beckurts and Runne[5] as a better indicator than phenolphthalein in the titration of the salts of such alkaloids as cocaine and also that in certain cases phenolphthalein may be used to better advantage as an indicator if the titration be carried out on an alcoholic solution of the alkaloidal salt instead of the aqueous solution, so that the means for estimating the salts of the alkaloids are still further increased and hence also the advantages of converting the alkaloid into a salt for the purpose of indirectly estimating the alkaloid. However, all these advantages, important as they may be, are nevertheless much more limited in practical application than appears to be the case with the application of the Volhard method for this same purpose. For as pointed out by Plugge[3] and as may be seen from the tabulated results given in the subsequent part of this paper, phenolphthalein does not in all cases afford the means for close quantitative estimation, so that in such cases the results thus obtained are of approximate value only and serve chiefly in indicating about how much standard silver nitrate it will be necessary to add in the subsequent estimation by the Volhard method. On the other hand, the procedure involving the Volhard method affords also the additional advantage of permitting the estimation to be carried out even where it is impossible or difficult to obtain a colorless solution of the alkaloidal residue or its salt—an occurrence which is quite frequently met with in alkaloidal assaying—since by converting the estimation of the alkaloid into a simple determination of the chlorine in sodium chloride which is what the procedure here described practically amounts to, we are no longer dependent on the alkaloidal properties of the alkaloid and hence where its presence interferes it usually may be got rid of by adding sufficient alkali to unite with all of the hydrochloric acid in the solution and filtering off the precipitated alkaloid; or the alkaloid, as well as other organic coloring matter may be got rid of by gentle ignition of the residue obtained on evaporating the solution containing the metallic chloride or the measured excess of standard silver solution. In the previous work[1] along this line, it was shown that this procedure is applicable to the alkaloids quinine, quinidine, cinchonine, cinchonidine, and strychnine. Now the results obtained with eight more alkaloids which are frequently met with commercially, namely, the alkaloids cocaine, morphine, codeine, narcotine, atropine, hydrastine, pilocarpine, and brucine, are presented.

General Mode of Procedure.

Solutions of the respective alkaloids in hydrochloric acid of approximately half-normal strength were carefully prepared so as to make the solution of fiftieth molar strength (one-fiftieth of the molecular weight in grams per liter) with respect to the alkaloid. Varying amounts (5 to 50 cc.) of these solutions were transferred into porcelain evaporating dishes and the latter with their contents placed on the water bath, where they were allowed to remain until the liquid had completely evaporated. To each residue there were then added 5 cc. of alcohol (99 per cent.), with which it was thoroughly stirred and mixed, and the liquid again allowed to completely evaporate on the water bath, when this treatment with 5 cc. of alcohol was repeated. In the case of the alkaloids previously studied, the remaining excess of hydrochloric acid was gotten rid of by simply allowing the residue to remain on the water bath three hours after the liquid had completely evaporated. This latter mode of getting rid of the remaining excess of hydrochloric acid while requiring a longer time than the alcohol treatment is nevertheless simpler in some respects since it requires practically no attention The chief reason, however, for adopting here the alcohol treatment is because it was found that in the case of some of the alkaloids (*e. g.*, cocaine) considerable of the combined hydrochloric acid is lost if the former procedure is applied. After the second evaporation with the alcohol, the residue was taken up with distilled water (usually 10 cc.), phenolphthalein added, and the acidity of the solution titrated with 0.1 *N* sodium hydroxide. Wherever precipitation occurred on addition of the alkali, the precipitated alkaloid was filtered off, washed with small amounts of water until on testing a drop of the filtrate with silver nitrate it was shown to be free from chlorine, and the chlorine in the solution determined by the Volhard method. The latter was carried out as follows: The solution was diluted to about

---

[1] *Loc. cit.*

70 cc. with distilled water, then acidified by adding 5 cc. of dilute (10 per cent.) nitric acid, and followed by a measured amount of standard silver nitrate solution which was a little (2 cc.) in excess of that theoretically required. The whole was then made up to a definite volume (100 cc.), filtered through a dry filter, and an aliquot portion (50 cc.) of the filtrate taken for the determination of the excess of silver remaining in solution. The filtering off of the precipitate which usually forms on adding the standard alkali is in most cases unnecessary but was here carried out with all the alkaloids in order to make the procedure more nearly uniform in all cases. With the comparatively larger amounts of brucine the color developed in the solution on addition of the nitric acid interferes in the subsequent determination of the excess silver. Hence in those cases an aliquot portion was evaporated to dryness on the water bath, the residue ignited, then taken up with hot dilute nitric acid and the excess of silver in the solution determined by means of standard thiocyanate in the usual way. The results obtained are given in the following tables.

Cocaine.—A 0.02 *M* solution of cocaine in dilute hydrochloric acid of approximately half-normal strength was prepared, containing 1.212 grams cocaine, $C_{17}H_{21}NO_4$, in 200 cc. The results obtained with this solution are given in Table I.

TABLE I.—EFFECT OF VARYING THE AMOUNT OF COCAINE ON THE CONSTANCY OF THE PROPORTION OF HCl IN THE ALKALOIDAL RESIDUE.

0.02 *M* cocaine taken. cc.	0.1 *N* NaOH required. cc.	0.1 *N* $AgNO_3$ required. cc.	Amount of HCl found.[1] Milligrams.	Theory for $C_{17}H_{21}NO_4.HCl$. Milligrams.

50	10.45	10.10	35.80	35.45

The results given in the accompanying tables show that at least fairly close results may always be obtained if we estimate the chlorine of the combined hydrochloric acid in the alkaloidal residue. It also appears probable that the application of the Volhard method to the estimation of alkaloids is limited only by the possible instability of the hydrochloride of the given alkaloid under the conditions adopted for getting rid of the excess of the uncombined acid. For estimating the actual amount of alkaloid in specimens of these alkaloids as obtained commercially or in the course of assay, we may therefore adopt the following procedure:

About 0.2 gram of the specimen to be examined is dissolved in an excess of dilute hydrochloric acid (about 20 cc. of 4 per cent.), the liquid completely evaporated on the water bath, the residue thoroughly stirred and mixed with 5 cc. of alcohol and the liquid again similarly evaporated. This treatment with 5 cc. of alcohol is repeated and the liquid again evaporated on the water bath. The residue is then taken up with distilled water (about 10 cc.), phenolphthalein added, and the acidity of the liquid titrated with standard alkali. This titration with alkali will in most cases indicate, at least approximately, the amount of hydrochloric acid that remained combined in the alkaloidal residue and hence may serve at least in indicating how much standard silver solution to add in the subsequent estimation of the chlorine by the Volhard method. Any precipitate formed on addition of the alkali is filtered off, washed with small amounts of water until a drop of the filtrate on testing with silver nitrate is shown to be free from chlorine. The filtrate is then diluted with distilled water to about 70 cc., acidified by adding 5 cc. of dilute (10 per cent.) nitric acid, and followed by a measured amount of standard silver nitrate solution which is judged to be a little in excess of that required to precipitate all the chlorine in the solution. The whole is then made up to definite volume (100 cc.) and filtered through a dry filter. To an aliquot portion (50 cc.) of the filtrate, 1 cc. of a 10 per cent. ferric alum solution is added, and the excess silver in the solution titrated with standard thiocyanate solution. Having determined the amount of hydrochloric acid and knowing that in the case of the alkaloids above mentioned 1 molecule of the hydrochloric acid is equivalent to 1 molecule of the alkaloid, we can of course calculate the actual amount of the latter in the specimen under examination. In the case of brucine, or in any other similar case where the color of the solution would interfere in determining the end reaction, an aliquot portion of the liquid may be evaporated to dryness on the water bath, the residue ignited, taken up with hot dilute nitric acid, and the excess silver in the solution titrated with standard thiocyanate in the usual way.

NEW BOOKS.

First Year Chemistry. By Wilhelm Segerblom, A.B., Instructor in Chemistry at the Philips Exeter Academy. The Exeter Book Publishing Company, Exeter, N. H. pp. xxv + 410. Price, $1.50.

This book is a departure from the ordinary textbook of chemistry, although a few others of its kind have recently appeared. It is essentially a laboratory outline containing directions for performing 169 experiments. Only about 75 pages are devoted to theoretical and general matters. Some descriptive material in fine print accompanies the experiments. The author states: "My plan is to use the inductive method rigorously in the first 90 experiments." The inductive method is then dropped and "is followed by the theory of chemistry, with experiments to illustrate the laws and principles; this comes at the middle of the year—a period now approved by many teachers. The theory of chemistry is followed by considerable descriptive chemistry, studied in the light of recent theoretical conceptions, but with the spirit of the inductive method still an unconscious guide. . . . . . My object has been to give the student a conception of chemistry from the point of view of the scholar and the thinker, rather than from the point of view of the crammer, *i. e.*, to teach *chemistry* rather than to teach *a text-book.*" This is all very well except that the average student falls somewhat short of the heights of the scholar and thinker, and, in the experience of the reviewer, he needs something more unified and systematic than the isolated observations derived from experiments in order to get a comprehensive idea of even elementary chemistry. The reviewer does not wish to disparage the inductive method, for it is most excellent when one has time for it and applies it judiciously in connection with a good text.

The experiments of the book before us are for the most part well selected, and the directions are clear and concise. The general outline, pp. 339–354, supplies a useful summary for the guidance of the scholar. The general method of treatment is, however, old-fashioned, as a few examples will show: Hydrate and hydroxide are employed interchangeably throughout, the author seemingly being unaware of the modern significance of the word hydrate. Bases are considered to be either metals, metallic oxides, or metallic hydroxides, pp. 317 and 344. The crude statements of Berthollet, p. 319, are overemphasized, while the subject of reversible reactions and chemical equilibrium receives but brief mention toward the close, p. 337, and it is only in the light of the latter that Berthollet's principles can be intelligibly treated. The method of treatment of molecular weights as derived according to Avogadro's hypothesis is inadequate, and molecular formulas of simple substances are used before any explanation of the reason therefor is given. All densities are referred to hydrogen as unity, and the whole subject is treated on the hydrogen basis instead of that of oxygen, as is the more modern custom. The conception of the gram-molecular-volume, which so simplifies this subject and also the solving of problems concerned with gas volumes, is not introduced at all.

Loose or inaccurate statements are not uncommon as for example, the definition of hydrolysis, p. 296, of acids, p. 343, and of combining number, p. 352, and the statement of Faraday's law, p. 332. Experiments like No. 102 do not give molecular weights, and there are a number of problems based upon it, p. 371. Among the examples of reduction pp. 341–2, under (4), only the action of copper upon nitric acid is commonly classed as reduction; and under (5) and (6) the reactions are simply dissociations. Experiment 168 does not give the amount of salt dissolved in 10 cc. of *water*, but the amount present in 10 cc. of the *solution*.

Simplified spelling is used in the case of a few words, as "tho" and "thru," without any attempt to carry out all of the recommendations of the Simplified Spelling Board. "Hight" occurs throughout instead of the more usual form "height."

The typography of the book is good, and the proof-reading was carefully done except on p. 324. The main divisions of the text on pp. 183, 219, and 265 are not well indicated. O. F. TOWER.

Anleitung zum Experimentieren in der Vorlesung über organische Chemie. Zum Gebrauche an Universitäten, technischen Hochschulen und höhere Lehranstalten, sowie zum Selbstunterricht für Studierende. DR HANS RUPE, a. o. Professor an der Universität Basel. Vieweg und Sohn: Braunschweig, 1909. pp. 130. Geheftet, Mk. 4.50; Lnwd, Mk. 5.40.

This is a collection of lecture experiments for those giving courses in elementary organic chemistry and, as indicated in the supplementary title, may also be used advantageously by the student as a laboratory guide in the preparation and study of organic compounds.

The experiments include the determination of carbon and hydrogen, of nitrogen and of molecular weights; the preparation and properties of a large number of typical carbon compounds illustrative of the more important groups and reactions, together with such other topics as the distillation of petroleum and of wood, illuminating and water gas, fermentation soap, candles, equilibrium in esterification, bread-baking, collodion and guncotton, and the like.

The selection of experiments is, on the whole, quite satisfactory, the material is well classified and arranged, and the descriptions generally clear and explicit. The preparation of such substances as mercury fulminate, nitroglycerol, zinc ethyl, and the like, is, however, fraught with too much danger to be commended for lecture room demonstration or for inclusion in a book to be used as a laboratory guide for beginners.

As every organic chemist well knows, the great handicap encountered in lecture demonstration in his chosen field is the length of time needed to carry out many of the most important reactions. Where this difficulty cannot readily be avoided, the author meets it either by showing in the lecture room only the final step in the reaction or by continuing the reaction through successive lecture periods. In reading over the description of the experiments, the inorganic chemist cannot fail to be impressed with the laborious and time-consuming character of many of them as compared with the numerous relatively simple and rapid ones available in his own field.

The book should prove useful to all teachers of organic chemistry.

MARSTON TAYLOR BOGERT.

Calculations of General Chemistry. WILLIAM J. HALE. New York: D. Van Nostrand Company. pp. 174. Price, $1.00.

This book is designed for use during the first year of the student's progress in the study of chemistry. It comprises the units of measure, and the calculations based on density and specific gravity; effect of pressure and temperature on gases; Avogadro's hypothesis; law of definite proportions; derivation of formulas; chemical equations; normal solutions; combination of gases by volume and closes with an appendix giving a table of logarithms. The treatment is clear and concise and the volume will be of service to students.

In the calculations of density the author uses oxygen as the standard. He says: "Formerly hydrogen, as the lightest substance served this purpose, and consequently the close relatiouship between densities and molecular weights was apparent. In recent times oxygen, with the value of 32, has been adopted as the basis of molecular weights by reason of the great importance of this element in its numerous combinations with other elements and for reasons that will be made clear after further considerations."

The reasons for making oxygen the standard for densities are no clearer than those for making it the standard for atomic weights. Hydrogen is the only standard that is rational and scientific and the use of oxygen as a standard leads the student to confusion only. It is unfortunate that, even among scientists, a fad or fancy promulgated by some man of prominence so often finds many eager followers. WM. L. DUDLEY.

An Introduction to Physical Science. By FREDERICK H. GETMAN. John Wiley & Sons, New York. 1909. Price, $1.50.

The author has written this little book to meet the difficulties of beginners in chemistry by giving, in logical order, the physical principles which are most important for an intelligent study of chemistry. Seventy-eight pages are devoted to mechanics, 35 of which are concerned with gases and liquids. Sixty pages are devoted to heat and thermodynamics, while light electricity and magnetism are considered in the remainder of the 250 pages. Each chapter is concluded with a number of good problems and questions. If a student were acquainted with the contents of this book he would be well prepared to take up a study of chemistry, but it is not plain just when there will be time to devote to a course of this kind, unless it is taken in lieu of the regular course in physics. This book raises an interesting question; namely, is it desirable to have the principles of physics given with a special view to the study of chemistry? There might seem to be some advantages in this from the standpoint of the teaching of chemistry. On the other hand, if the student is held strictly accountable for everything he has had in physics, rather than attempting to give it to him in a somewhat different way, he would frequently need to get out his physics and do some independent thinking in applying the principles to the new things presented to him. This would be a gain in many ways: it would emphasize the importance of thorough work for future use, it would give more time for things more strictly chemical and good students would not be bored with an elementary presentation of things with which they were already familiar. Wherever this method is possible it certainly would tend to develop more thinking by the student in chemistry, a point that is of first importance.

G. A. HULETT.

The First Principles of Chemical Theory. By C. H. MATHEWSON. John Wiley & Sons. pp. 123. Price, $1.00.

This book of 123 pages is used by the author as a supplementary text to a short course of lectures which follow the first four months' work in general chemistry. The purpose is to introduce the student to the principles of chemistry very early in his course with the idea of continually repeating and illustrating these principles as the student accumulates facts in his subsequent work. Besides the subjects generally touched upon in a course in general chemistry, the student is introduced to the subject of osmotic pressure and related phenomena, electrolytic dissociation theory, heterogeneous equilibrium, thermochemistry and the many terms and conceptions accompanying these subjects. When the student once gains a working knowledge of these things his work will become mentally interesting and very much more intelligible and profitable, so it is desirable to have these things as early in the course as possible. On the other hand, any real conception of these principles should be based on an intimate (laboratory) knowledge of some facts. Without this the principles are merely so many words and when introduced again the student remembers having heard about them, while on repetition he may come to dislike the subject and so lose the mental training and pleasure that should go with a study of chemistry. This unfortunate result is alltogether too frequently encountered in third- and fourth-year students, and it emphasizes the importance of determining just what basis of fact is necessary to afford a working conception of a given principle. The increasing favor of quantitative experiments in general chemistry laboratory work is an expression of this need, and it would seem that the rational development of the instruction in chemistry must give considerable attention to questions as to just when a particular principle is to be introduced so that it may stimulate the reasoning powers and be an effective tool in the further study. The compact statements in which the principles of chemistry are expressed afford rather poor material for a memory exercise. It would seem, therefore, to be desirable to develop the principles and theories, at least during the whole course of undergraduate chemistry, rather than in a single course of lectures. G. A. HULETT.

Elements of Mineralogy, Crystallography and Blowpipe Analysis, from a practical standpoint including a description of all common or useful minerals, the tests necessary for their identification, the recognition and measurements of their crystals, and a concise statement of their uses in the arts. By ALFRED J. MOSES and CHARLES LATHROP PARSONS. Fourth edition, vii + 444 pages, 580 figures and three double pages of tables for determinative mineralogy. New York: D. Van Nostrand Company. Price, $2.50.

The fourth edition of this well-known book differs but very slightly from the third edition (1904). Some changes in the introductory chapter, a few paragraphs added, and the statistics of production and value revised are the only changes noted. The main body of the text, descriptive of the mineral species, has not been changed. For instance, molybdite is still stated to be MoO_3 (page 277), and thorianite is not mentioned at all. While it is always difficult to decide on what to include and what to exclude from "all common or useful minerals," it would seem more desirable to include a mineral like dumortierite which has been found in this country in five different states, rather than such rare ones as aikinite, aphthitalite, etc. It must be somewhat confusing, particularly to a student, for whom the book is specially adapted, to find under pyroxene, crystal drawings of "fassaite" and "leucaugite" (Figs. 518 and 519), neither of which is mentioned in the text or in the index. The brief mention of many of the not very common yet still not very rare minerals would be a slight improvement on this otherwise excellent book, which gives, as the extended sub-title briefly indicates, about all the essential facts of mineralogy. W. T. SCHALLER.

Annuaire pour l'An 1910. Published by the Bureau des Longitudes. 16 mo., 820 pages. Paris: Gauthier-Villars, 1910. Price, 1.50 francs.

As cheap as before, as full of inaccuracies as usual. In the immense amount of information given upon astronomical, geographic, physical and chemical phenomena, the larger part is of course correct, but a short search brings to light so many inaccuracies that the work as a whole must bear the stigma of being unreliable, at least as regards physical and chemical data. In one place, a column of chemical equivalents of the elements is headed "electrochemical equivalents." In a table of atomic weights and chemical equivalents, antimony, arsenic, nitrogen, bismuth, boron, phosphorus and silicon are considered as *monovalent* elements, aluminium is bivalent (!), while vanadium with an atomic weight of 51.2 has an equivalent weight of 68.5 (!!). Inaccurate values determined by French experimenters are frequently given to the exclusion of greatly more accurate ones by non-Gallic scientists. As a scientific compilation, in the proper sense of the term *scientific*, it is discreditable to the authors and to France.

JOSEPH W. RICHARDS.

A System of Diet and Dietetics. Edited by G A. SUTHERLAND. London, 1908. xiii + 893 pp. Price, $7.50.

This volume, which is one of the series entitled Oxford Medical Publications, contains a number of papers by different authors on food and nutrition in health and disease. Among the papers of special interest to students of nutrition may be mentioned: "A Discussion of General Principles," by Sir Lauder Brunton; "The Evolution of Man's Diet," by Dr. Harry Campbell; "The Physiology of Digestion, Absorption, and Nutrition," by Dr. E. I. Spriggs; "The Results of Experimental Work on Diet," by Dr. E. I. Spriggs; "Diet Cures and Special Diets," by Dr. Edmund Cautley; "Patent and Proprietary Foods," by Dr Edmund Cautley; "Diet in Old Age," by Dr. Harry Campbell; and "The Feeding of Infants and Children in Health," by Dr. G. A. Sutherland.

In the chapter on the Evolution of Man's Diet, the epochs which the discussion treats are: The simian period, the homo-simian period, the early hunting period, the pre-cibicultural cookery period, and the cibicultural period, or the period in which man has depended upon cultivated crops for food. Dr. Campbell has brought together a large amount of information not generally accessible and has rendered a service to all students of dietetics by the clear and systematic way in which the evolution of man's diet is discussed.

All the sections are of decided interest and value as they represent the views of men of wide experience in the subjects treated as well as summaries of data fundamental to adequate discussion of such questions. The chapters on diet in disease are of unusual interest to the medical practitioner. As stated in the editor's preface "this book is not a reflection of the fancies of the public on the subject of their food, or of the methods of the individual who believes in an infallible system for dieting of his patients. Until our knowledge of physiology is more perfect than at present the scientific basis of dietetics must be an unstable one. Nevertheless patients must be dieted, and the physician must be guided by the teaching of history, by experimental physiology, and by clinical experience in the proper regulation of their diet. All that has been attempted in this book is to set down the principles and practice of men who have had special experience in the subjects on which they write."

C. F. LANGWORTHY.

Die Methoden zur Herstellung Kolloider Lösungen Anorganischen Stoffe. By Dr. The. Svedberg. Published by Theodor Steinkopff, Dresden. 500 pp. 16 Marks, unbound.

This extensive work is confined to the methods of preparation and is not a general treatise on colloidal solutions. All known methods of inorganic colloid preparation are thoroughly and systematically treated. They are divided into condensation and dispersion methods. The former are again divided into reduction, oxidation, hydrolysis and other condensation methods. The latter are divided into mechanical-chemical and electrical dispersion methods. Each of these subdivisions is taken up separately and the descriptions are preceded by very complete literature references. Under the electrical dispersion method is given a well illustrated description of the author's improvement of Bredig's method. An oscillatory discharge with large electrical capacity produces the colloidal metal much more rapidly than does the application of the simple direct current, as described by Bredig. The book is a very complete treatment of the methods of preparation of inorganic colloids, and suggests the need of a similar separate treatise on organic colloids and one on properties and characteristics of colloids. American Chemical Society

SOME CHEMISTRY OF LIGHT.[1]

BY W. R. WHITNEY.

From the dawn of history, chemistry has had much to do with the production of artificial light, and I wish now to recall to your minds a few illustrations I will not burden your ears with a long story on physics or mechanics of light, but intend treating the subject of artificial light so as to show you that it has always been largely a subject for chemical investigation I want to impress upon your minds that it is still a most green and fertile field for the chemist. I have tried to arrange a few familiar experiments to illustrate some of the facts touched upon, and it should be borne in mind that I am trying to interest an audience of chemists from widely different fields, rather than to present a chronological record of recent experimental research.

I cannot tell just when chemistry was first scientifically applied to a study of artificial light. Most cardinal discoveries are made by accident and observation. The first artificial light was not made by design nor was the first improvement the result of chemical analysis. It is supposed that the first lamps were made from the skulls of animals, in which oil was burned. Herodotus, describing events about three centuries before Christ, says of the Egyptians: "At the times when they gather together at the city of Sais for their sacrifices, on a certain night they all kindle lamps many in number in the open air round about the houses; now the lamps are saucers full of salt and oil mixed and the wick floats of itself on the surface and this burns during the whole night." This night was observed all over Egypt by the general lighting of lamps, and these lamps were probably the forerunners of the well-known Greek and Roman lamps of clay and of metal which are so common in our museums.

---

[1] Presidential address delivered at the Boston Meeting of the American Chemical Society, December 29, 1909.

The candle and lamp were probably invented very much earlier. We know that both lamps and candles were used by the priests of the Jewish temple as early as 900 B. C. The light of those candles and lamps was due, as you know, to particles of carbon heated in a burning gas.

It is not fair to the chemists of our early candle-light to skip the fact that great chemical advances were made while candles were the source of light, and so I touch for a moment upon one of the early applications of chemical knowledge. The fats and waxes first used were greasy and the light was smoky and dull. They were capable of improvement and so the following chemical processes were developed and applied to the fats. They were first treated with lime, to separate the glycerol and produce a calcium soap. This was then treated with sulphuric acid, and the free stearic and palmitic acids separated. These acids were then made into candles and gave a much whiter light than those containing the glycerol ester previously used. Similar applications of chemical principles are probably known to you all in the refining of petroleum. The crude distillate from the rock oil is agitated with sulphuric acid and then washed with a solution of sodium hydroxide. This fact accounts, in considerable degree, for the advance of a number of other chemical processes. An oil refinery usually required the presence of a sulphuric acid plant in the immediate vicinity, and this often became a source of supply for other new chemical industries.

Very great advances have been made in the use of fats and oils for lighting purposes, but there is so much of greater interest in later discoveries that we will not consider many of them. The distillation of gas from coal or wood in 1739 was a chemical triumph, and a visit to a gas plant still forms one of the main attractions to the young chemist in an elementary course of applied chemistry. The first municipal gas plant was established in London, just about 100 years ago. The general plan, so apparently simple to us to-day, was at its inception judged impracticable by engineers. In spite of other methods of illumination, the improvements in the making, purification and application of illuminating gas have caused a steady increase in its use. Gas owes its illuminating power to the fact that a part of the carbon in it is heated to incandescence during the combustion of the gas. It must contain, therefore, such carbon compounds as yield a fair excess of carbon, and this knowledge has led to the schemes for the enrichment of gas and for the use of non-luminous water-gas as a base for illuminating gas.

Various schemes were devised in the early part of the 19th century for using gas to heat to incandescence, rods or surfaces of lime, zirconia and platinum. This was not at first very successful, owing to imperfect combustion of the gas. The discovery of the Bunsen-burner principle was made a little later. By thus giving a much higher temperature to the gas flame and insuring complete combustion, this gave new impetus to this branch, and the development of suitably supported oxide mantles continued for half a century.

Most prominent in this field is the work of Auer von Welsbach. It was a wonderful series of experiments which put the group of rare-earth oxides into practical use and started a line of investigation which is still going on. The Welsbach mantle practically substitutes for the carbon of the simple gas flame, another solid in a finely divided shape capable of giving more efficient light. This allows all of the carbon of the gas to contribute to the production of a hotter flame. But more interesting than the mechanical success, to my mind, is the unforeseen or scientifically unexpected discovery of the effect of chemical composition. By experiment it was discovered that the intensity and color of the various mixtures of difficultly fusible oxides at incandescence varied over a wide range. Thus a broad field for unforeseen investigation was opened. The samples of Welsbach mantles which you see before you were kindly loaned to me by Mr. H. S. Miner, of the Welsbach Company, and beautifully illustrate the application of advanced chemical work to this industry. The color and intensity of the light varies in an unexplained manner with slight differences in composition of the mantle. The following are the composition and candle powers of the mantles shown:

CANDLE POWER OF MANTLES, RANGING FROM PURE THORIA TO 10 %CERIA.

No.	Per cent. thoria.	Per cent. ceria.	Candle power.
367	100.00	0.00	7
368	99.75	0.25	56
369	99.50	0.50	77
370	99.25	0.75	85
371	99.00	1.00	88
372	98.50	1.50	79
373	98 00	2.00	75
374	97.00	3.00	65
375	95.00	5.00	44
376	90.00	10.00	20
69		La, Zr, Ce, oxides,	30

The methods of making present mantles were also a part of Dr. Auer's contribution to the art. Suitably woven fabrics are dipped into solutions of the rare-earth salts; these are dried and the organic matter burned out, leaving a structure of the metal oxides.

The pure thoria gives a relatively poor light. The addition of the ceria, up to a certain amount, increases the light. This added component is called the "excitant," and as the cause for this beneficial action of the excitant is not known, it is possible that further discoveries along this line will yet be made. There is hardly a prettier field for chemical speculation than is disclosed by the data on these light efficiencies. For some unknown reason, the change in composition by as little as one per cent. varies the luminosity over tenfold, and yet, more than one per cent. of the excitant (ceria) reduces the light. Besides the temptation to speculation, such disclosures of Nature encourage us to put greater trust in the value of new experiments, even when accumulated knowledge does not yield a blazed trail for the pioneer. By giving a discovery a name and attaching to it a mind-quieting theory, we are apt to close avenues of advance. Calling this small amount of ceria an "excitant" and guessing how it operates, is directly harmful unless our guess suggests trial of other substances.

One of the explanations proposed to cover the action of the ceria ought to be mentioned, because it involves catalysis. This is a term without which no chemical lecture is complete. Some think that the special mantle mixture causes a more rapid and localized combustion and therefore higher temperature, by condensation of gas in its material. Others think that this particular mixture permits of especially easy and rapid oxidation and reduction of its metal oxides themselves in the burning gas mixture. The power which catalyzers have of existing in two or more states of oxidation seems to apply also to the ceria of the Welsbach mantle. Whatever the truth may be, it has been shown by Swinton[1] that when similar oxide mantles are heated to incandescence by cathode rays *in vacuo*, the presence of one per cent. ceria produces only a very small increase in the luminosity of thoria. It is interesting to note that in the gas flame pure ceria gives about the same light as pure thoria, while in the cathode rays of the Crookes tube, with conditions under which ceria gave almost no light, pure thoria gave an intense white light. These facts, which are still unexplained, illustrate how little is understood in this field.

I will merely refer to the fact that vapors of gasoline, kerosene, alcohol, etc., are also now used in conjunction with the Welsbach mantles.

The field of acetylene I must also omit with a mere reference to the fact that the manufacture of calcium carbide was a chemical discovery and the action of water upon it, producing the brilliantly-burning acetylene gas, was another.

Turning now to electrical methods of generating light, we find the chemist early at work. Sir Humphry Davy and others, at the dawn of the 19th century, showed possibilities which since that time have been developed into our various types of incandescent and arc lamps. We naturally attach Mr. Edison's name to the development of the carbon incandescent lamp, because it was through his indefatigable efforts that a practicable lamp and illuminating system were both developed. It had long been known that platinum, heated by the current, gave a fair light, but it melted too easily. A truly enormous amount of work was done in attempts to raise the melting-point of the platinum, and the effect of occluded gases, of annealing, of crystalline condition, etc., etc., were most carefully studied, but the results were unsatisfactory. He was therefore led to the element carbon as the next most promising conductor of high melting point. Edison's persistent and finally successful attempt to get a dense, strong, practical filament of pure carbon for his lamps, is one of the most encouraging lessons to the chemist of to-day. This history needs to be read in the light of the knowledge of carbon at that time and the severe requirements of a commercially useful carbon filament. It illustrates the value of continued effort when it is based on knowledge or sound reasoning. The search was not the groping in the dark that some of us have imagined, but was a resourceful search for the most satisfactory, among a multitude of possible materials. From our point of view, all subsequent changes in choice of material for incandescent lamp filaments have been indicated by the knowledge that high melting point and low vapor-tension were the first requirements. If you will consult the curve of the *melting points* of all the *elements*, as plotted against their *atomic weights*, you will see at once that the desired property of high melting point is a periodic functionof the atomic weight. And it is this fact, which was independently disclosed as a general law by Meyer and Mendeléeff, in 1863, that has aided in the selection of all the new materials for this use. You will notice that the peaks of the curves are occupied by such elements as carbon, tantalum, tungsten, osmium, etc., which are all lamp materials.

---

[1] *Proc. Roy. Soc., London* (*A*), 65, 115.

A study of the laws of *radiation* also soon played a part in incandescent lamp work. The early rough and black filament of bamboo was first replaced by a polished black carbon filament, and later by one which had a bright, silver-gray coat of graphite. A black body at any temperature radiates the maximum possible energy in all wave lengths. Heated to incandescence, it will *radiate more invisible and useless infra-red rays than any other* opaque material at the same temperature. A polished metal is therefore a more efficient light source than the same metal with a black, or even rough surface. This is derived from Kirchoff's Law of Radiation and Absorption, which was early established.

It may seem like penetrating too far into detail to consider for a moment the changes in structure and surface which the carbon filament of our incandescent lamps has undergone, but the development of such an apparently closed problem is instructive because it has yielded to such simple methods of attack. The core, or body, of the carbon filament of to-day is made by some one of the processes based on dissolving and reprecipitating cellulose, such as are used in artificial silk manufacture. The cellulose solution is squirted through a die into a liquid which hardens it into dense fibers. These cellulose fibers are then carbonized by being heated, out of contact with the air, at as high a temperature as possible with gas furnaces. All of this is also merely the application of chemistry which was first worked out in some of the German chemical laboratories. This plain carbon filament, the result of this simple process which might have been satisfactory in the early days, would be nowadays useless in a lamp, as its practical life is only about 100 hours at 3 watts per candle. In a subsequent process of manufacture it is therefore covered with a steel-gray coating of graphite, which greatly improves the light-emitting power. This coat is produced by heating the filament in an atmosphere of benzene or similar hydrocarbons. The electric current which heats the filament is of such an intensity that the decomposition of the hydrocarbon produces a smooth, dense deposit of graphite. With this graphite coat the filament now burns about 500 hours; but the simple graphite coat can itself be improved. It is improved by being subjected, for a few moments, in the electric furnace, to a temperature of about 3500°, so that the life now becomes about 1500 hours under the same operating conditions as before. The product of this treatment is known as the metallized filament, because its temperature coefficient of resistance is by this last step made similar to that of the metals.

A case is shown on the table which contains illustrations of the carbon incandescent lamp manufacture in the shape of cellulose solution, squirted cellulose fiber, carbonized fiber, etc.

Among the incandescent lamps which are before you I have one containing a platinum wire filament. You will see, as I turn on the current, that the intensity of its light is not very great, even when the current is sufficient to melt the wire. A much greater luminosity is produced by a plain carbon filament, and a still greater by the graphite coated and metallized carbon before they are destroyed. In the case of carbon, the useful life of the lamp depends much more on the vaporization of the material than on its melting point, and these lamps, as shown, will operate for a short time at very much greater efficiencies or higher temperatures than is possible when a practical length of life is considered. Thus, besides the physical effect of surface quality, we have evidence of differences in the vapor pressure of different kinds of carbon. It looks as though carbonized organic matter yielded a carbon of much greater vapor pressure for given temperature than graphite, and that even graphite and metallized graphite are of quite distinctly different vapor pressures at high temperatures. It may be interesting to note here that if the carbon filament could withstand for 500 hours the maximum temperature which it withstands for a few moments, as shown in the experiments, then the cost of operating incandescent lamps could be reduced to nearly a fifth of the present cost.

It was discovered by Auer von Welsbach that the metal osmium could be made into a filament, though it could not be drawn as a wire. The osmium lamp was the first of the recent trio of metallic filament incandescent lamps. The tantalum lamp, in which another high melting point metal replaces the superior but more expensive osmium, has been in use six or eight years. This surpasses the carbon in its action, and on running up to its melting-point it shows still brighter light than carbon. More recently the tungsten filament lamp has started to displace both lamps. At present this is the element which withstands the highest temperature without melting or vaporizing, and on being forced to its highest efficiency in a lamp you see that it reaches higher luminosity and that there is a similarity to carbon and tantalum in that an enormously greater efficiency may be produced for a very short time than can be utilized for a suitable length of life. The inherent changes at these temperatures, distillation or whatever they are, quickly destroy the lamp. The lamp will burn an appreciable time at an efficiency fifteen times as great as that of the common operating carbon incandescent lamp (at 3 watts per candle). In other words, light may be produced for a short time at an energy-cost one-fifteenth of common practice, so that there is still a great field for further investigation directed towards merely making stationary those changing conditions which exist in the burning lamp.

While it is generally true that the light given by a heated body increases very rapidly with rise of temperature above 600°, the regularity of the phenomenon is commonly overestimated. A certain simple law covering the relation between the temperature and the light emitted, has been found to apply to what we have called a black body. This so-called Stefan-Boltzmann law states that "the total intensity of emission of a black body is proportional to the fourth power of the absolute temperature." There are, however, very few real black bodies in the sense of the law. The total emission from a hole in the wall of a heated sphere has been shown experimentally to follow the law rigidly,* but most actual forms and sources of illumination do not. Most practical sources of artificial light are more efficient light producers than the simple law requires. This may be said to be due to the fact that these substances have characteristic powers of emitting relatively more useful energy as light than energy of longer wave length (or heat rays). Most substances show a power of selective emission and we might say that an untried substance, heated to a temperature where it should be luminous, could exhibit almost any conceivable light effect. It is still less possible to predetermine the proportionality between luminous and nonluminous emission. A simple illustration will serve to make this clear: if a piece of glass be heated to 600°, it does not emit light. If some powder such as zirconia or thoria be sprinkled upon it, light is emitted and the proportion of light at the same temperature will depend upon the composition of the powder. Coblentz has shown, both for the Auer mantle and for the Nernst glower, that the emission spectra are really series emission bands in that portion of the energy curve which represents the larger part of the emitted energy. This is in the invisible infra-red part, and so the laws which govern the emission at a given temperature depend upon the chemical composition of the radiant source. Silicates, oxides etc., show characteristic emission bands.

One of the most attractive fields of artificial light production has long been that of luminous gases or vapors. It has seemed as though this ought to be a most satisfactory method. The so-called Geissler tubes in which light is produced by the electrical discharge through gases at low pressure are familiar to all. The distribution of the energy emitted from gases is still further removed than that of solids from the laws of a black body, and a large proportion of the total electrical energy supplied to a rarefied gas may be emitted as lines and bands which are within the range of the visible spectrum. These lines, under definite conditions of pressure, etc., are characteristic of the different elements and compounds. The best known attempts to utilize this principle are the Moore system of lighting, in which long tubes of luminous gas are employed, and the mercury lamps, which, while more flexible on account of size, are still objectionable because of the color of the light. A simple form of mercury arc is shown.

It is rather interesting that the efficiencies of all of these various sources of electric light are not nearly so widely different as one would expect from a consideration of the widely divergent methods of light production employed.

From the light of a vapor or gas to that of an open arc is not a wide step, but the conditions in the arc are apparently quite complex and there is a great deal of room for interesting speculation in the phenomena of an arc. Briefly, there are two kinds of arcs to be considered in lighting. One has been in use for a century, the other for a few years only. The first is the successor to Sir Humphry Davy's historical arc between charcoal points. In this kind of arc the current path itself is hardly luminous and the light of the lamp is that given by the heated electrodes. In case of direct current it is the anode, or positive electrode, which gets the hotter and gives far the greater part of the light. In the carbon arc shown, it will readily be seen that the light is emitted by the heated solid carbon of one electrode. This gives a steady source of light, but is not so efficient as an arc in which material in the arc stream itself is the source of light. The arc may be made to play upon rare earth oxides, and these, being heated to incandescence, increase the luminosity, but this has not proved useful. The more common way is to introduce into the carbon electrode certain salts which volatilize into the arc and give a luminous effect. Here cerium fluoride, calcium fluoride, etc., are used, and the color of the arc, just as in the case of gas mantles, may be varied by varying the composition of the electrodes. This is seen in the arc from the carbon electrodes containing such salts.

I have arranged several different kinds of arcs and before each is a magnifying lens, to throw the image of the arc upon a screen. This permits our seeing the phenomena of the arcs and observing the characteristics of each. The very essential difference between the plain carbon arc and the luminous or flaming arc is readily noticed. In the latter case the greater part of the light is due to the incandescent metallic vapors in the space between the electrodes. Substitution of one chemical for another in such flaming arc electrodes has covered quite a wide range of chemical investigation. Salts are chosen which give the greatest luminosity without causing the formation of too much ash or slag. Some compounds of calcium, for example, are practicable, while others are not, though all of these would, under suitable conditions, yield the calcium spectrum.

If such salts as calcium fluoride were conductors at ordinary temperature, useful electrodes for flame arcs would probably be made from them. Such conducting materials as iron oxide, carbides, etc., have been used for flame arc electrodes, and a great many of the so-called magnetite arcs are now in use. The electrodes in this case are largely magnetic oxide of iron, with such other ingredients as titanium and chromium oxides, to increase the intensity of light, to raise the melting point of the mixture, etc.

As will be seen from observing this arc, the light is very white and intense and is generated by the heated vapors of the arc proper. A great many modifications of this arc principle are possible. Titanium carbide and similar substances give characteristic arcs, and some of them are very intense and efficient. For purposes of comparison, I have added to this illustrating experiment an arc of titanium carbide and one of copper.

The Nernst Lamp.

A distinct species of electric incandescent lamp is that invented about 10 years ago by the well-known physical chemist, Professor Nernst. This employs for filaments a class of bodies which are not electrical conductors at all at ordinary temperatures, and which, at their burning temperatures, do not conduct the current as metals and carbon, but as a solution does. This kind of conductivity, the electrolytic, involves electrochemical decomposition at the electrodes, and in the case of the Nernst filaments these otherwise destructive reactions are rendered harmless by the continual oxidizing action of the air. For this reason this type of lamp will not burn *in vacuo*. For its most perfect utility the principle of the Nernst lamp seems to require a mixture of oxides, because a single one is not so good a conductor nor so luminous. It uses oxides because these are the most stable compounds known, and it uses the rare-earth oxides because they have higher melting points than other oxides. As the efficiency very rapidly rises with the temperature, there is a great advantage in using the most infusible base possible. For that reason, zirconia, thoria, etc., are usually employed.

In this lamp a rod or filament of an oxide mixture, much like those used in Welsbach mantles, is heated by the current externally applied until it reaches a temperature at which it becomes a good conductor itself. Here again the peculiar laws of light radiation are illustrated, the light emitted at a given temperature being determined by the nature of the substance. Just as the pure thoria gives a poor light compared to the mixture with one per cent. ceria, so a pure zirconia rod, heated by the current, gives much less light than a rod containing a little thoria, ceria or similar oxide.

Work done by Coblentz on the energy-emission of such rods shows the emission spectra, at least in the infra red, to vary with the nature of the substance. In general, the spectra are not continuous like the spectra of metals and black bodies, but seem to occupy an intermediate position between these and luminous gases, which we know have usually distinct line spectra.

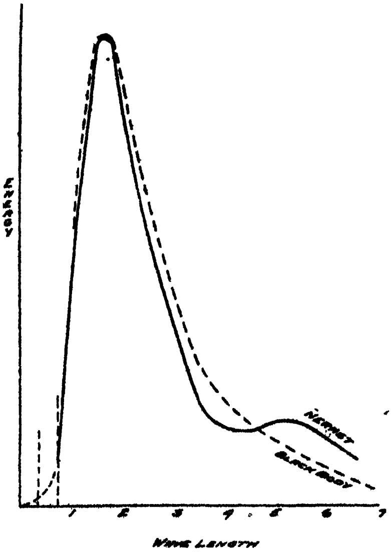

Fig. 1.

This recalls the subject of selective emission. Coblentz has shown selective emission in the long wave lengths for a Nernst glower. This is shown in comparison with the emission of a black body, in curve Fig. 1. The two sources, when compared at the temperatures where they exhibit the same wave length for maximum emission, differ very considerably in emission in the infra red, the black body giving more energy at the blue end, and less at the red end of the spectrum.

This is still more noticeable in the curves for such substances as porcelain, magnesia and glass, as shown by Coblentz's curves (Fig. 2).

The curves of wave length and radiant energy which are shown are, with slight modifications, taken from work of Lummer and Pringsheim and of Dr. Coblentz. The curve for the ideal, or black-body radiator, gives a picture of the total energy and its distribution over the different wave lengths. It is the peculiarity of the black body to radiate more energy of any given wave length than does any other body at the same temperature. Therefore, in case of all substances acting as thermal radiators, the black body will always give the greatest brilliancy. Since this body at the same time radiates a maximum in *all* wave lengths, it will be surpassed in light *efficiency* by any substance which is a relatively poor radiator in the invisible or non-luminous part of the spectrum.

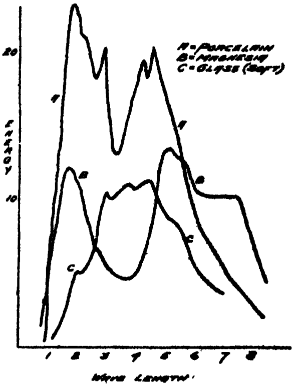

Fig. 2.

In the energy curves shown it is to be noticed that the visible part of the energy is practically only that between 0.4 and 0.8 thousandths of a millimeter. Consider the black lines in Fig. 3 for a moment. These show the emission of a black body at centigrade temperatures noted on the curves. Evidently the energy emitted rises very rapidly with the temperature; *i. e.*, as the 4th power of the absolute temperature. It will be noted also that the point of maximum energy or wave length corresponding to maximum energy shifts gradually toward the left or towards the visible wave lengths.

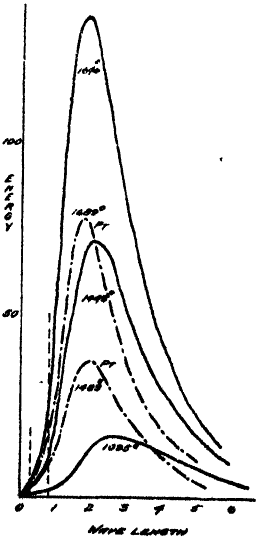

Fig. 3.

It is this rapid shifting of the position of maximum energy which makes the search for substances which can withstand even only slightly higher temperatures, of such great interest.

The curves for the black body and for platinum (dotted lines, Fig. 3), are not greatly different in general appearance, but the total amount of energy emitted at a given temperature from the black body is shown to be more than for the platinum, and it can be seen that at about the same temperature the platinum is the more economical light source. Prof. Lummer has said that at red heat, bright platinum does not radiate *one-tenth* the total energy which the ideal black body radiates at the same temperature, and at the highest temperature still less than one-half. The deviation of platinum from the black body law is a step in the direction of getting improved light-efficiency without corresponding increase of temperature. This method is practically without limit in its extension, for there seems to be no limit to the forms of energy curves which different substances may possess. The curves are apparently determined not only by physical state, but also by the chemical composition of the emitting substance.

You see before you a vacuum incandescent lamp which contains a ribbon of platinum, in the shape of a loop. While the section of the platinum is the same throughout, one-half of the loop is blackened by depositing a little platinum black upon it. This greatly affects the light efficiency as shown. The blackened portion, being more nearly a black body, radiates at each temperature relatively more energy of long wave length (*i. e.*, heat) than the bright portion; so for about equal total energy radiated the ribbon radiates less as light from the blackened surface.

In the production of artificial light, the tendency will always be in the direction of increasing the practical efficiency; *i. e.*, reducing the cost of light. We have seen that there is still much room for this. In the case of the kerosene oil lamps we know that much less than one per cent. of the energy of combustion of the oil is radiated as light from the flame. In the case of the most efficient source, the electric incandescent lamp at highest efficiency, we are still far from ideal efficiency. A still higher temperature would yield a yet higher efficiency. We do not know exactly how much light might possibly be yielded for a given consumption of energy, but one experimenter concludes that it is about ten candles per watt. If this is true, even the most efficient light you have seen this evening is less than half as efficient as it might be. Fortunately, it is not now clear just how the chemist is to realize all the advances which he will make in more efficient lights.

No consideration of this part of the subject is complete without a brief reference to the efficiency of the firefly. The source of his illumination is evidently chemical. This much is known about the process.

The light-giving reaction is made to cease by the removal of the air, and to increase in intensity by presence of pure oxygen. It is extinguished in irrespirable gases, but persists in air some time after the death of the insect. Its production is accompanied by the formation of carbon dioxide. These all indicate a chemical combustion process. Prof. Langley has shown that such a flame as the candle produces several

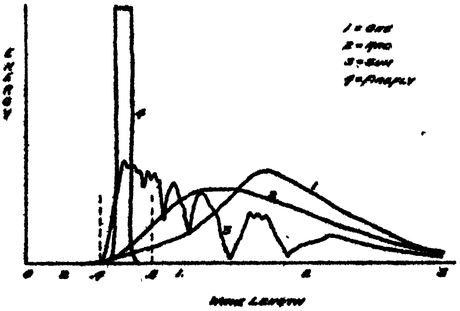

Fig. 4.

hundred times as muchus eless heat as the total radiation of the firefly for equal luminosity. In other words, the firefly is the most efficient light source known. This is illustrated by the energy distribution curves from several light sources taken from Prof. Langley's work (Fig. 4). The difficulties attendant upon the accurate determination of the curve for the firefly are so great that we ought not to expect very great accuracy in this case. These curves, which in each case refer to the energy after passing through glass, which cuts off energy of long wave lengths, represent the same quantities of radiant energy. While the sun is much more efficient than the gas flame or carbon arc, it still presents far the largest part of its energy in the invisible long wave lengths (above 0.8), while the firefly seems to have its radiant energy confined to a narrow part of the visible spectrum.

Summary of the Results on the Hydrolysis of Ammonium Acetate and on the Ionization of Water, Ammonium Hydroxide, and Acetic Acid.

1. Outline of the Investigation.

In a paper from this laboratory published six years ago[1] an apparatus and method were described by which accurate measurements of the electrical conductivity of aqueous solutions could be made at temperatures up to 306°. In a second paper[2] were presented the results of the measurements of the conductivity of aqueous solutions of various salts, bases, and acids, and the ionization relations of these substances were discussed. The purpose of the research to be described in this article was to study another phenomenon—that of the hydrolysis of salts into

[1] THIS JOURNAL, 26, 134–170 (1904).

[2] *Ibid.*, 30, 335–352 (1908).

free acid and base—by measuring the change of conductance produced by adding an excess of the weak acid or base. Since the degree of hydrolysis is dependent on the degree of ionization of the water, this important quantity can be computed from it, when the knowledge of the hydrolysis is supplemented by that of the ionization of the acid and base involved. In this research there have been made measurements of the hydrolysis of ammonium acetate and of the ionization of ammonium hydroxide and acetic acid at temperatures of 100, 156, 218, and 306°.

The method employed for determining the hydrolysis is in principle that described first by Walker,[1] and later in more exact form by Bredig.[2] It consists in measuring the change in conductance produced by adding to the salt solution, in which the salt is partially hydrolyzed, a sufficient quantity of the slightly ionized acid or base to reduce the hydrolysis appreciably, and in computing, from the change produced by different quantities of acid or base added, the degree of hydrolysis. In this case it was practicable to reduce the hydrolysis by the addition of an excess both of the acid and of the base, since both are only slightly conducting substances; and in this case there results an increase in conductance corresponding almost exactly to that of the new quantity of ammonium acetate produced out of the free acid and base originally present.

The calculation of the ionization constant of water from the hydrolysis of the salt involves, as stated, a knowledge of the ionization constants of the acid and base. The determination of the former quantity therefore involves measurements of the conductance at various concentrations of solutions of the following substances; ammonium acetate; ammonium acetate with varying proportions of ammonium hydroxide and of acetic acid; ammonium hydroxide; acetic acid; ammonium chloride; sodium acetate; sodium chloride; sodium hydroxide; and hydrochloric acid. Measurements with dilute solutions of the last five substances are needed for the computation of the equivalent conductance at zero concentration of ammonium hydroxide and acetic acid. The results of such measurements with the last three substances have been previously published in THIS JOURNAL. The data for ammonium chloride and sodium acetate will be presented in this article.

2. Apparatus and Method of Procedure.

The conductivity cell used was like that previously described.[3] It consisted of a platinum-lined steel bomb, through the bottom of which passed a platinum electrode insulated from the bomb by being supported upon a quartz cylinder or by being contained in a quartz cup.

[2] *Ibid.*, 13, 214–321 (1894).

[3] THIS JOURNAL, 26, 135–141 (1904).

The method of making the measurements was also in general similar to that followed in the previous researches in this laboratory. For a full description of the experimental procedure, of the preparation of the substances and analysis of the solutions, of the corrections applied for the conductance of the water and for contamination, and of all other experimental details, and also for a record of the original observations, the reader is referred to the more complete publication of this work which has been issued by the Carnegie Institution of Washington.[1] In this briefer article only the final results and the computations and conclusions based upon them will be presented.

3. Equivalent Conductance of Ammonium Chloride and Sodium Acetate.

Since ammonium chloride and sodium acetate are appreciably hydrolyzed at high temperatures (thus in 0.01 normal solution about 1.6 per cent. at 218° and 3.4–4.1 per cent. at 306°), the conductance of these salts was measured (except at 18 and 25°) in the presence of a greater or less proportion of ammonium hydroxide or of acetic acid;[2] and from the result was subtracted the conductance of the base or acid calculated from the ionization constants (given in Section 6) with the aid of the mass-action relations, $C_{OH} = K_B.C_{NH_4OH}/C_{NH_4}$ and $C_H = K_A C_{HAc}/C_{Ac}$. The measurements with ammonium chloride at 18, 100, and 156° were made by Prof. Yogoro Kato; at 18, 25, 218, 306° by Dr. R. B. Sosman; those with sodium acetate were made at 18, 100, 156 and 218° by Dr. H. C. Cooper;[3] and at 306° by Dr. R. B. Sosman.

Table 1 contains the final values derived from all these measurements by correcting the observed data for all known sources of error, so that they represent only the conductance of the pure unhydrolyzed salts. The concentration given in the second column represents the number of milli-equivalents of salt contained in one liter of solution at the temperatures corresponding to the conductance values given in the following columns. The latter are expressed in reciprocal ohms. In regard to the values at zero concentration see the next section. The temperatures are those on the hydrogen-gas scale (based at 218 and 306° upon the results of Jaquerod and Wassmer[4]).

	80	63.4	...	221.0	340	452	..

4. Equivalent Conductance at Zero Concentration of the Various Substances.

The values of the equivalent conductance (Λ_0) at zero concentration for ammonium chloride and sodium acetate were obtained by extrapolation with the aid of the equation $C(\Lambda_0 - \Lambda) = K(C\Lambda)^n$. This when written in the form $1/\Lambda = 1/\Lambda_0 + K_1(C\Lambda)^{n-1}$ may be conveniently employed graphically by plotting $1/\Lambda$ against $(C\Lambda)^{n-1}$, the exponent $n - 1$ being taken equal to that value in the neighborhood of 0.5 which is found by trial to give most nearly a straight-line graph.[2] The values of Λ_0 for these two substances, already given in Table 1, are reproduced in Table 2, together with those previously determined for the various other substances which are needed in calculating the values of Λ_0 for ammonium hydroxide and acetic acid by means of the relations:

$$\Lambda_0(NH_4OH) = \Lambda_0(NH_4Cl) + \Lambda_0(NaOH) - \Lambda_0(NaCl)$$

$$\Lambda_0(HC_2H_3O_2) = \Lambda_0(NaC_2H_3O_2) + \Lambda_0(HCl) - \Lambda_0(NaCl).$$

The determinations of Λ_0 for sodium chloride, hydrochloric acid, and sodium hydroxide (up to 156°) have been previously described in THIS JOURNAL.[3] The value for sodium hydroxide at 218 and at 306°, where no measurements or no sufficiently accurate measurements exist, was derived under the assumption that it lies at such a proportional distance between the Λ_0 values for sodium chloride and hydrochloric acid at these temperatures as is indicated by its position between them at the lower temperatures of 18, 100, and 156°.

---

[1] This same value (within 0.1) was obtained entirely independently by Prof. Kato and Dr. Sosman, and also by the latter on two separate preparations obtained respectively by recrystallizing the solid salt and by neutralizing ammonium hydroxide and hydrochloric acid.

[2] The exponent for ammonium chloride was assumed to be the same as for potassium chloride at those temperatures where it was not possible to determine it owing to the fact that the measurements did not extend to a higher concentration than 12.5 millinormal.

[3] Vol. 30, p. 339.

TABLE 2.—EQUIVALENT CONDUCTANCE AT ZERO CONCENTRATION.

Substance.	18°.	100°.	156°.	218°.	306°.
NH_4Cl	130.9	415	628	841	1176
$NaC_2H_3O_2$	78.1	285	450	660	924
$NaCl$	109.0	362	555	760	1080
$NaOH$	216.5	594	835	1060	1310
HCl	379	850	1085	1265	1424
NH_4OH	238	647	908	1141	1406
$HC_2H_3O_2$	348	773	980	1165	1268

5. The Equivalent Conductance of Ammonium Hydroxide and Acetic Acid.

In deriving the final values of the equivalent conductance of ammonium hydroxide and acetic acid, all appropriate corrections were applied to the observed data, including that for the conductance of the water and for the small proportion of the ammonia oxidized during the heating. The ammonia used was obtained from two sources—by diluting a specially prepared commercial sample of ammonia water and by distilling liquid ammonia which had stood in contact with sodium. Great care was taken to avoid contamination by the carbon dioxide of the air.

The final values, expressed in the same way as in Table 1, are presented in Table 3. The measurements with acetic acid at 100 and 156° and some of those at 218° were made by Dr. H. C. Cooper, some of those at 218° and all at 306° by R. B. Sosman. Those with ammonium hydroxide at 100 and 156° were made by Yogoro Kato, at 18, 218 and 306° by R. B. Sosman.

TABLE 3.—FINAL VALUES OF THE EQUIVALENT CONDUCTANCE OF AMMONIUM HYDROXIDE AND ACETIC ACID.

Substance.	Concentration.	18°.	100°.	156°.	218°	306°.
NH_4OH	10.0	9.66	23.25	22.31	15.56	...
	30.0	5.66	13.58	12.99	...	...
	80.0	3.47	...	...	5.39	...
	100.0	3.103	7.47	7.17	4.82	1.329
	300.0	1.752	...	...	...	0.785
	500.0	1.325	...	...	...	...
$HC_2H_3O_2$	10.0	14.50	25.10	22.15	14.70	...
	30.0	8.50	14.70	12.95	8.65	...
	80.0	5.23	9.05	8.00	5.39	...
	100.0	4.68	8.10	..	4.82	1.57
	300.0	2.68	...	...	...	0.84

Values were also obtained for ammonium hydroxide at 100 milli-normal at three temperatures between 18 and 100° and at 125°. These values are as follows:

25°.	50°.	75°.	125°.
3.62	5.35	6.70	7.76

Entirely independent determinations made in this laboratory at different times by Messrs. Yogoro Kato, R. B. Sosman, and C. W. Kanolt have given for 100 millinormal ammonium hydroxide at low temperatures closely concordant values, namely, 3.10, 3.10, and 3.11 at 18°, and 3.62 and 3.61 at 25°. Concordant results were also obtained independently by H. C. Cooper and R. B. Sosman for 100 millinormal acetic acid at 18°, namely 4.67 and 4.685.

6. The Ionization of Ammonium Hydroxide and Acetic Acid.

The values of the ratio 100 Λ/Λ_0 corresponding to the percentage ionization (100γ) are given in Table 4. They were obtained by dividing the Λ values given in Table 3 by the appropriate Λ_0 value given in Table 2.

TABLE 4.—PERCENTAGE IONIZATION OF AMMONIUM HYDROXIDE AND ACETIC ACID.

The values for 100 millinormal ammonium hydroxide at the intermediate temperatures are as follows:

25°.	50°.	75°.	125°.
1.338	1.34	1.27	1.02

The values of the ionization constants were calculated from these data by the expression $K = (C\gamma)^2/C(1 - \gamma)$, C being here expressed in equivalents per liter. They are brought together in Table 5. Best values valid for dilute solutions have also been derived, regard being paid to the greater experimental errors in the more dilute solutions and to the deviation from the mass-action law in the more concentrated ones. These are given in italics at the foot of each series.

It is evident from these results that the ionization constant for ammonium hydroxide increases considerably in passing from 0 to 18°, then remains nearly constant up to 50°, and finally decreases with increasing rapidity as higher temperatures are reached, attaining at 306° a value which is only about one two-hundredth of that at 18°. It is also evident that at all temperatures the values for acetic acid are not very different from those for ammonium hydroxide.

7. Conductance of Ammonium Acetate Solutions at 18, 100 and 156°.

Experiments by YOGORO KATO.

The hydrolysis experiments were made by measuring the specific conductance of ammonium acetate solutions containing in one case the salt alone and in other cases the salt together with varying quantities of ammonium hydroxide and acetic acid. In the experiments at the temperatures up to 156°, the observed values of the specific conductance were corrected to round temperatures with the help of temperature coefficients derived from the measurements themselves and then further corrected to uniform concentrations by assuming direct proportionality between the concentration and specific conductance through the small concentration interval involved. The so-reduced values are presented in Table 6. In the columns headed "Initial" are given the equivalent conductances obtained from the measurement at the temperature in question before going to the higher temperatures, while in the columns headed "Final" are given the equivalent conductances obtained after returning to the temperature in question from the higher ones. A comparison of these initial and final values in the separate experiments shows the contamination or destruction of the substance that resulted from the heating.

The final data needed for the computation of the hydrolysis, and the calculated values derived from them are presented in Table 7. The column headed L_M contains the most probable values of the specific conductance derivable from the separate values of Table 6, taking into account the contamination and applying a correction for it. In the next column under L_{HA} or L_{BOH} is given the conductance of the acetic

---

acid or ammonium hydroxide present. This was obtained by first calculating C_{OH} or C_H from the mass-action equations

$$\frac{C_B C_{OH}}{C_{BOH}} = K_B \text{ or } \frac{C_A C_H}{C_{HA}} = K_A,$$

by substituting for C_B or C_A the ratio $L_{BA}/\Lambda_{0\,BA}$ of the specific conductance of the ammonium acetate (BA) to its equivalent conductance when completely ionized, and then multiplying the value of C_{OH} or C_H

by $\Lambda_{0\,BOH}$ or $\Lambda_{0\,HA}$. The difference of the values of L_M and L_{HA} or L_{BOH} given in these two columns gives the specific conductance L_{BA} of the salt in the mixture. This is given in the sixth column, and in the seventh column is given the calculated conductance of the salt (L_S) when present in water alone at the same concentration as it has in the mixture. The last column headed $L_{BA} - L_S$ gives the increase of conductance caused by the reduction of the hydrolysis produced by the addition of the base or acid.

8. Hydrolysis of Ammonium Acetate and Ionization of Water at 100 and 156°.

From Table 7 it will be seen that the excess of base or acid causes an increase in the conductance of about 5 per cent. at 100° and 15–21 per cent. at 156°. It will also be seen that at 100° the addition of a quantity of acid or base equivalent to the salt produced as great an increase as a larger quantity, showing that the hydrolysis had been reduced substantially to zero. The effect of the acid was, as it should be, nearly equal to that of the base, the small differences observed being doubtless due to experimental error. The percentage increase was also nearly the same at the two concentrations of the salt (4.6 and 4.9 per cent.) respectively, showing that the hydrolysis does not increase much with the dilution, which is what the mass-action law requires for a salt whose acid and base are both weak. At 156° the second equivalent of acid or base produces a large further increase in conductance, showing that the salt is still somewhat hydrolyzed. Here again the acid and base have not far from the same effect, as they should have on account of the smallness of their ionization constants.

The quantitative calculation of the ionization at 100° is comparatively simple. Since the hydrolysis is reduced to zero by the added acid or base, the increase in specific conductance produced by it when divided by the equivalent conductance Λ_0 (338) of the completely ionized salt gives at once the number of equivalents per cubic centimeter of free acid and base which have been converted into ions. In addition a quantity of the un-ionized salt, corresponding to the increased concentration of its ions, is produced out of the acid and base. To compute this, we have made use of the equation $\frac{(C\gamma)^n}{C(1-\gamma-h)} = K$ (where γ is the fraction ionized and h the fraction hydrolyzed), in which we have determined the constants n and K from the conductances (L_{BA}) of the unhydrolyzed salt (7141 and 2990×10^{-6} at the two concentrations (24.92 and 9.97 milli-equivalents per liter) investigated and from the Λ_0 value for the salt. We have then calculated from the values of L/Λ_0 (which are equal to $C\gamma$) the concentration of un-ionized salt, $C(1-\gamma-h)$, both in the solution containing the salt alone and in that to which acid or base had been added.

The excess of the second value over the first value gives the un-ionized salt, $\Delta C(1-\gamma-h)$, that has been produced out of free acid and base: this added to the quantity ($\Delta C\gamma$) of ions similarly produced gives the quantity of salt in the hydrolyzed state when it is alone present in water; and this divided by the concentration (C) gives the fraction hydrolyzed (h_0). The results of the computations are given in Table 8.

TABLE 8.—HYDROLYSIS OF AMMONIUM ACETATE AND IONIZATION CONSTANT OF WATER AT 100°.

C.	100γ or $100 L_S/C\Lambda_0$	$\Delta(C\gamma)$ or $(L_{BA}-L_S)/\Lambda_0$	$\Delta(C(1-\gamma-h))$.	Ch_0.	$100h_0$.	$K_W \times 10^{14}$.
24.92	82.2	0.94	0.21	1.15	4 61	48.5
9.97	85 9	0.411	0 064	0.475	4 76	47.4

It will be seen from Table 8 that the hydrolysis h_0 is only a little greater at 10 than at 25 millinormal. From each of these values the ionization-constant of water ($K_w = C_H \times C_{OH}$) has been calculated, and the results are given in the last column, the concentration being here expressed in equivalents per liter. The calculation was made by means of the mass-action expression $K_w = K_A K_B h^2/\gamma^2$ in which K_A and K_B are the ionization-constants of the acid and base respectively, and h and γ are the hydrolysis and ionization of the salt when present in water alone. This expression is obtained by multiplying together the two ionization equations $K_A = C_H C_A/C_{HA}$ and $K_B = C_B C_{OH}/C_{BOH}$, substituting K_w for $C_H C_{OH}$, γC_S for C_A and C_B, and $C_S h_0$ for C_{HA} and C_{BOH}, and transposing. It will be noted that the two independent values of K_w agree almost completely.

In order to calculate the hydrolysis at 156° from the conductance data it is necessary, since the hydrolysis is not reduced to zero even by the largest quantity of acid or base added, to unite with the empirical relation between the concentrations of ions and un-ionized molecules, the mass-action relation between the concentration of the ions and the products of the hydrolysis. These two expressions, if γ represents the fraction of the salt existing as ions and h the fraction hydrolyzed into free acid and base and C_S and C_{BOH} are the concentrations of the salt and of the added base (or acid) respectively, are

$$\frac{(\gamma C_S)^n}{C_S(1-\gamma-h)} = \text{const.} \qquad (1)$$

and

$$\frac{(\gamma C_S)^2}{(C_{BOH}+C_S h)C_S h} = \frac{\gamma^2}{(C_{BOH}/C_S+h)h} = \frac{K_A K_B}{K_W} = \text{const.} \qquad (2)$$

Or, representing by γ_0 and h_0 the ionization and hydrolysis of the salt when in water alone, and by γ_1 and h_1 these same quantities when the concentration of the salt is the same, but base (or acid) is present in excess at a concentration C_{BOH} and writing r for C_{BOH}/C_S we have:

$$\left(\frac{\gamma_1}{\gamma_0}\right)^n = \frac{1-\gamma_1-h_1}{1-\gamma_0-h_0} \quad (3) \quad \text{and} \quad \left(\frac{\gamma_1}{\gamma_0}\right)^2 = \frac{h_1(r+h_1)}{h_0^2} \quad (4)$$

two simultaneous equations which can be solved for h_0 and h since the other quantities may be derived from the measurements. Thus the ratio γ_1/γ_0 is equal to L_{BA}/L_S (see Table 7), and the separate values of γ_1 and γ_0 are given by the quotients $L_{BA}/C_S\Lambda_0$ and $L_S/C_S\Lambda_0$, Λ_0 being equal to 523. For the exponent n we assumed provisionally the value 1.5, which is that for sodium acetate at this temperature; but after the hydrolysis had been computed for the two different salt concentrations it was obtained by direct application of equation (1) to the mean of the two sets of results, and was thus found to be 1.45; and with this new value of n the calculations were repeated, although this variation in n produced a decrease in h_0 of only 0.7 per cent. of its value both at 23.68 and at 9.473 millinormal. Equations (3) and (4) can be completely solved algebraically for h_1 or h_0, but it is far simpler to use only the incomplete solution obtained by taking the logarithm of equation (3) and eliminating h_0 from it by means of equation (4), whereby results the expression:

$$\log \frac{1-\gamma_1-h_1}{[(1-\gamma_0)\gamma_1/\gamma_0]-\sqrt{h(r+h)}} = (n-1)\log\frac{\gamma_1}{\gamma_0}.$$

This equation can be readily solved for h_1 by trial, and h_0 can then be calculated by (4).

The results of the calculations are given in Table 9. The headings will be understood by reference to the preceding paragraph. In computing the ionization constant of water, which was done as before by the expression $K_W = K_A K_B\, h_0^2/\gamma_0^2$, the concentration was expressed in equivalents per liter and the values of K_A and K_B used were 5.67×10^{-6} and $6.28 \times$

10^{-6}, respectively. The letter A after the value of the ratio $r(= C_S/C_B)$ signifies that acetic acid, the letter B, that ammonium hydroxide, was present in excess.

An examination of the values of K_w given in the last column of Table 9 shows that those derived from the experiments where acetic acid was added agree closely with one another not only in case of the successive additions of the acid but also at the two different concentrations of the salt, while those from the experiments where ammonium hydroxide was added are far less concordant whether considered with respect to the successive additions (in the second series) or to the different salt concentrations. This fact, taken in conjunction with the experience that the base solutions are far more liable to contamination, justifies the adoption of the value 223×10^{-14} derived from the experiments with the acid as the best final value for the ionization constant of water at 156°. It is worthy of note, however, that the mean value 229×10^{-14} derived from the experiments with the base is less than 3 per cent. higher than this.

9. Conductance of Ammonium Acetate Solutions at 18, 218 and 306°.

Experiments by R. B. SOSMAN.

The final values for the specific conductance of ammonium acetate solutions at 218 and 306° will next be presented. The observed data were first reduced to round temperatures by means of directly determined coefficients, and were then corrected for the conductance of the impurities

in the water, for that of the water itself, and for that of the added base or acid. The last two corrections, which never exceeded 0.25 per cent., were computed with aid of the ionization constants of the three substances.

Table 10 contains the so-corrected data for the pure salt, and Table 11 those for the salt with an excess of base or acid. In the latter table are given for 218° and 306° in two additional columns (1) the specific conductance (L_0) which the pure salt has at the same concentration as that (C) of the salt in the mixture, and (2) the ratio of the specific conductance (L) of the salt in the mixture to this conductance L_0. The specific conductance L_0 is calculated from that given in Table 10 for nearly the same concentration under the assumption of proportionality between conductance and concentration through the small interval involved.

10. Hydrolysis of Ammonium Acetate and Ionization of Water at 218 and 306°.

From the data given in Table 11 the hydrolysis of the salt at 218 and 306° was calculated by two different methods.

The first method was that employed by Noyes and Kato and described in Section 8 of this article.

In the second method the ion concentration is, as before, calculated by dividing the specific conductance of the solution (multiplied by 10^3) by the equivalent conductance of the completely ionized salt; and then the concentration of the un-ionized salt is estimated under the assumption that it has the same value as in a solution of an ordinary unhydrolyzed salt of the same ionic type at the same ionic concentration. Then merely by subtracting the un-ionized fraction (u) and the ionized fraction (γ) from unity, the hydrolyzed fraction (h) is obtained; that is, $h = 1 - \gamma - u$. In this calculation the mean value of the ionization of potassium and sodium chlorides was used as a basis. This calculation can give accurate hydrolysis values only when the hydrolyzed fraction is large and the un-ionized fraction very small; but under such conditions, which are in fact realized in the foregoing experiments fairly well at 218° and in much higher degree at 306°, it is the most direct method and a fairly reliable one.

Table 12 contains the results of the calculations. In the fifth and sixth columns are given the values of the percentage hydrolysis ($100\,h$) calculated by the first and second methods, respectively. In the seventh column is given a mean derived from these. Since the results by the second method are more accurate the greater the hydrolysis, in deriving this mean a weight has been assigned to them equal to the percentage hydrolysis, the results by the first method being always given a weight of 100. It is desirable to combine the results by the two methods in some such way as this, since any error in the conductance ratio L/L_0 influences them in opposite directions. In the last three columns of the table are given the values of the percentage hydrolysis ($100\,h_0$) of the salt in pure water at the same concentration C. The values in the first of these columns are derived by the first method simultaneously with those of $100\,h$. Those in the second of these colums are calculated from the mean value of $100\,h$ given in the seventh column by the equation $h_0^2 = \dfrac{h(h + C_B/C)}{(L/L_0)^2}$. Those in the last column are obtained directly by the second method from the conductance in pure water.

A comparison of the values of the percentage hydrolysis ($100\,h$) of the salt in the mixture calculated by the two methods shows at 218° a considerable divergence, especially in the experiments where an excess of base was added. This was doubtless due largely to the destruction of some of the base during the heating. At 306° where this was determined and allowed for, and where the calculation by the second method is more accurate, the agreement is far more satisfactory (except in the first experiment which appears to be affected by some accidental error). From an examination of the values of the percentage hydrolysis ($100\,h_0$) of the salt in pure water it is seen that the experiments in which different

quantities of acid were added gave very concordant results, whether calculated directly by the first method or from the weighted mean value of the percentage hydrolysis (100 h) for the salt in the mixture. The mean value calculated from the latter is, however, to be considered the most accurate. It will be seen that this agrees well in all cases with the value given in the last column, which was calculated directly by the second method from the conductance of the salt in pure water. To get the best final value from each group of experiments we have combined these two by assigning to the former a weight of 100 and to the latter a weight equal to the percentage hydrolysis. Table 13 contains the final hydrolysis values so obtained, the ionization values for the salt, the ionization-constant of water calculated from them by the equation $K_W = K_A K_B h_0^2/\gamma_0^2$, and the square root of this constant, which represents the concentration C_H of the hydrogen (or hydroxide) ion in pure water.

11. Summary of the Results on the Hydrolysis of Ammonium Acetate and the Ionization of Water, Ammonium Hydroxide, and Acetic Acid.

The final values of the percentage hydrolysis of ammonium acetate in 0.01 normal solution, of the ionization constants of ammonium hydroxide, acetic acid, and of water ($K_W = C_H C_{OH}$), and of the equivalents (C_H) of hydrogen ion or hydroxide ion present in one liter of pure water, obtained as described in this article, are summarized in Table 14. We have also included in the table values of the ionization constant of water at 0, 18, and 25° derived by Dr. C. W. Kanolt[1] from experiments made by him in this laboratory upon the conductance of ammonium hydroxide and of diketo-tetrahydrothiazole and upon the hydrolysis of the salt of this base and acid, in order to enable the results at the higher temperatures to be compared and combined with these at lower temperatures. The value given in the table for the hydrolysis of ammonium acetate at 18° is not based on direct measurements, but has been computed from the ionization constants of water, ammonium hydroxide, and acetic acid at that temperature.

---

156	18.6	223	14.9	6.28	5.36
218	52.7	461	21.5	1.80	1.72
306	91 5	168	13.0	0.093	0.139

It will be seen that the hydrogen-ion concentration in pure water increases with extraordinary rapidity between 0 and 100°; namely, by about 3-fold between 0° and 25° and 7½-fold between 25 and 100°. Between the latter temperature and 218° the ionization increases more slowly, afterwards passes through a maximum (which appears to lie between 250 and 275°), and finally decreases. When it is considered that the ionization of weak acids and bases, as shown by the data for ammonium hydroxide, acetic acid, and phosphoric acid, decreases rapidly with rising temperature, and that this acts in the same direction in increasing the hydrolysis of salts as does an increase in the ionization of water, it will be evident that the tendency of salts to hydrolyze is enormously greater at high temperatures, as is well illustrated by the values given for ammonium acetate.

The great increase in hydrolysis is also exemplified by the hydrolysis values for sodium acetate and ammonium chloride in 0.01 normal solution that can be calculated from the preceding data: these salts, which at 18° are 0.02 per cent. hydrolyzed, are found to be 1.6 per cent. at 218° and 3.4 to 4.1 per cent. hydrolyzed at 306°.

The fact also deserves mention that the values of the concentration of the hydrogen ion in water at 0, 18, and 25° as derived from Kanolt's hydrolysis experiments are 16 to 20 per cent. lower than those obtained by Kohlrausch and Heydweiller[1] from the conductance of their purest water, and by Lunden[2] from his hydrolysis experiments.

From these ionization constants (K_w) approximate values of the internal-energy increase ΔE attending the reaction $H_2O = H^+ + OH^-$ (the so-called heat of ionization) can be computed by the familiar equation[3] derived from the Second Law of Energetics: $d \log K_w/dT$

---

[1] *Ann. Phys.*, [3] 53, 209 (1894); [4] 28, 511 (1909).

[2] Publications of Nobel Inst., 1, No. 8, p. 16 (1907).

[3] This equation ceases to be even approximately exact at high temperatures where the vapor pressure of water becomes very large. The exact expression, which may be derived through the consideration of an appropriate cyclical process, is as follows:

$\Delta E/RT^2$. This is best done by integrating it under the assumption that ΔE is a linear function of the temperature as expressed by the equation $\Delta E = \Delta E_0 + \alpha RT$. The integral then has the form

$$\log \frac{K_2}{K_1} - \alpha \log \frac{T_2}{T_1} = \frac{\Delta E_0}{R} \frac{T_2 - T_1}{T_1 T_2}.$$

From the values of the ionization constant K at 0°, 25°, and 100°, the values of the constants ΔE_0 and α have been found to be 28460 and —24.923, respectively. Therefore, the general equation for the energy increase attending the ionization becomes

$$\Delta E = 28460 - 49.5\,T,$$

and that for the ionization constant becomes

$$\log_{10}(10^{16}K) = 84.450 - \frac{6222}{T} - 24.923 \log_{10} T.$$

The values of the energy increase in calories and of the ionization constant of water as calculated by these expressions are given in Table 15.

TABLE 15.—INTERNAL-ENERGY INCREASE ATTENDING THE IONIZATION OF WATER AND ITS IONIZATION CONSTANT CALCULATED BY AN EMPIRICAL EQUATION.

Temperature.	Energy increase. ΔE.	Ionization constant $K \times 10^{14}$.
0	14950	0.088
18	14055	0.46
25	13710	0.81
50	12470	4.5
75	11230	16.9
100	9995	48
128	8610	114
156	7225	217
218	(4155)	(512)

These values of the ionization constant at 0, 25, and 100° necessarily agree with the directly determined ones given in Table 14. It is of interest to note, however, that this is also true of the calculated value at 156°, which shows that up to this temperature the assumed equations hold

$$\Delta E = RT^2 \frac{d \log Kw}{dT} + \Delta V . T^2 \left[\frac{d(p/T)}{dT} - \frac{d(P/T)}{dT} \right]$$

where ΔE is the energy increase and ΔV is the volume increase that attends the ionization of one mol. of water under the pressure $p - P$, which is substantially identical with the vapor pressure p, since the osmotic pressure P is in this case negligible in comparison. Approximate values of ΔV up to 140° have been computed by Tammann (*Z. physik. Chem.*, **16**, 144 (1894)) which show it to be equal to about —26 cm. at 140°; and since it is shown to be increasing at a rate roughly proportional to the compressibility of water, it probably has a value in the neighborhood of —40 cm. at 218°. Assuming this to be the case, the last term in the above equation can, with the help of the existing vapor-pressure data, be shown to have a value of about —170 calories at 218°, while the value of ΔE as computed by the linear equation is 4155 at 218°. Thus at temperatures above 200° this last term begins to form a substantial part of the whole.

true, and that therefore the values interpolated for the intermediate temperatures between 0 and 156° are doubtless substantially correct. Even at 218° the difference between the observed and calculated values (461 and 512), though doubtless real, is not very large; it lies in such a direction as to indicate that the energy change ΔE is decreasing at a more rapid rate at temperatures above 156° than at the temperatures below it. This is also shown by the fact that the ionization constant at 306° is much less than at 218°, while according to the linear equation the value of ΔE should become zero, and therefore that of the ionization constant K should become a maximum, very near the former temperature, namely, at 302°. The real maximum value of the constant seems to lie between 250 and 275°. Above this temperature ΔE assumes a negative value; and therefore the neutralization of completely ionized acids and bases would be attended by an absorption of heat.

It may also be mentioned that at the lower temperatures the calculated values agree well with the heat of neutralization directly measured by Wörmann,[1] who found for hydrochloric and nitric acids when neutralized with potassium and sodium hydroxides as mean values 14,710 calories at 0° and 13,410 calories at 25°.

It seems worth while to call attention to a possible theoretical explanation of the fact that water, unlike all other substances thus far investigated, continues to increase in ionization up to so high a temperature as 250 or 275°. This phenomenon may well arise from the facts that water at low temperatures is a highly associated liquid containing only a small proportion of H_2O molecules, and that this proportion increases rapidly with rising temperature. Therefore, even through the fraction of H_2O molecules dissociated into H^+ and OH^- ions may decrease steadily, yet the actual concentration of these ions continues to increase until a large proportion of the complex water molecules have been depolymerized.

To the Carnegie Institution of Washington we desire to express our great indebtedness for the financial assistance by which the execution of this investigation has been made possible.

BOSTON, November, 1909.

THE REACTION BETWEEN AMMONIUM CHLORIDE AND POTASSIUM DICHROMATE WHEN HEATED.

BY G. B. FRANKFORTER, V. H. ROEHRICH AND E. V. MANUEL.

Received December 8, 1909.

Doubtless every one who has given a course of lectures in general chemistry has used the potassium dichromate and ammonium chloride method for the preparation of nitrogen, inasmuch as this is one of the methods mentioned in nearly all of the old as well as in some of the new texts of inorganic chemistry. One of us using this method some years ago had reasons to question the correctness of the reaction as ordinarily given:

---

[1] *Ann. Physik.*, [4] 18, 793 (1905).

$$2NH_4Cl + K_2Cr_2O_7 = Cr_2O_3 + 2KCl + 4H_2O + N_2.$$

The matter was not carefully examined until some time later when the subject was taken up and carefully investigated. It required but a few experiments to show that the gas liberated by heating a mixture of ammonium chloride and potassium dichromate is not pure nitrogen. On the contrary, it contains, in addition to nitrogen, such amounts of nitric oxide and nitrogen peroxide as would make the simple equation given above entirely out of the question. In fact, the gas obtained is so rich in nitric oxide that when exposed to the air the brown peroxide color becomes very distinct. It was found, on looking up the literature, that Ramon de Luna,[1] in a letter to Dumas, first described the method and is responsible for the above equation. He intimated, however, that the nitrogen obtained was not pure unless passed through a solution of iron sulphate. It is evident from this last statement that he was aware of the presence of the oxides of nitrogen, although no mention of their presence was made and no attempts made to determine the quantity of gas liberated. From a number of analyses made under widely varying conditions, the writers have concluded that the above reaction is only correct in so far as water, some potassium chloride and some nitrogen are formed in the reaction. Chromic oxide is formed only after prolonged heating at a comparatively high temperature. Nitric oxide and nitrogen peroxide are probably formed when the mixture is heated at any temperature above 210°.

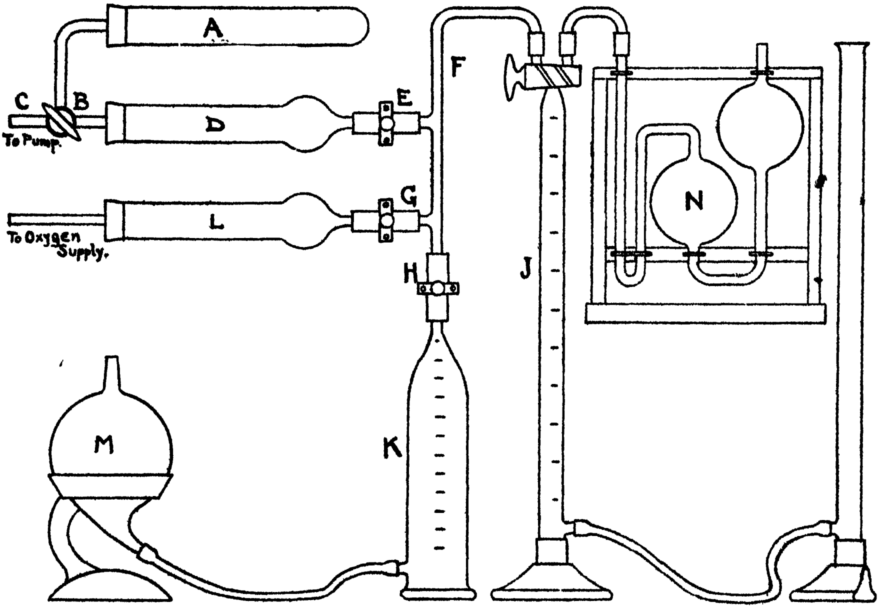
The gas first examined was prepared by using the quantities of salts recommended by de Luna, namely, equal parts of ammonium chloride and potassium dichromate and heating in a hard glass tube containing a delivery tube for collecting the gas over water. In these first experiments we were unable to detect nitrogen peroxide in the gas liberated, doubtless on account of its solubility in water. Later when the gases were collected over mercury, nitrogen peroxide was always found, varying, however, from a very small quantity to 3.5 per cent. Nitric oxide varied from 3 to 50 per cent. of the total gas liberated.

In our first experiments, great difficulty was experienced in preparing the gas for analysis, as it was necessary to remove every trace of air from the apparatus before the analysis was begun. After many experiments with different forms of apparatus, the following figure was constructed and used in most of the subsequent analyses: The hard glass tube A is connected with drying tube D by means of the three-way cock B; tube C is connected with an air pump. D is connected with F by means of a heavy rubber connector and pinchcock, E. F is connected with gas burette J, gas holder K, and drying tube L, for furnishing pure oxygen. The leveling tube M is connected with holder K by means of a heavy rubber tube. J is connected with gas pipette N by means of a three-way cock.

---

[1] *Ann. chim. phys.*, [3] 68, 183.

To prepare the gas for analysis, the hard glass tube A was filled with the mixture of ammonium chloride and potassium dichromate and connected with B. Gas burette J and reservoir K were filled with mercury up to the capillary tube F. Stopcock B was turned so that A and D were in connection with the air pump. The air was then exhausted and the apparatus washed out twice with pure nitrogen prepared from ammonium nitrite. Finally a vacuum of less than one millimeter was obtained and the experiment begun by gradually heating A. The gases first liberated were collected in the reservoir K until a sufficient quantity was obtained for examination, analysis being made of the gas liberated at different temperatures, beginning at 210°.



Analysis of the Gas.—As both nitric oxide and nitrogen peroxide were present, a method for the determination of these gases was used, depending upon the fact that nitrogen peroxide is soluble in potassium hydroxide, while nitric oxide is not. All the determinations in the first table of analyses were made over mercury with Hempel's apparatus for the exact analysis of gases over mercury. The nitrogen peroxide was first removed by means of caustic potash. The nitric oxide was then determined by adding to the residue a known volume of pure oxygen, and noting the change in the combined volumes as indicated by the following equation:

$$2NO + O_2 = 2NO_2.$$

Finally the results were checked by absorption of the nitrogen peroxide formed by means of potassium hydroxide.

In collecting the gas, preparatory to analysis and during the process of analysis, difficulties arose on account of the nitrogen peroxide attacking the mercury. We were unable to completely prevent this although by carefully drying the gases before coming in contact with the mercury, the action was greatly reduced. The following table gives the percentage by volume of the total amount of gas liberated on heating equal parts of the salts to a dull red heat:

TABLE I.

	N.	NO.	NO_2.
1.	55.3	41.1	3.1
2............	55.6	42.2	2.2
3	54.6	44.0	1.4
4..	50.1	48 5	1.4
5	54.3	44.6	1.1
6	48.7	50.1	1.2
Average......	53.1	45.1	1 7

An average of twenty analyses gave numbers differing but slightly from the above average. The first two analyses were made without completely evacuating the apparatus before heating. This doubtless accounts for the increased amount of nitrogen peroxide. It is not possible that the peroxide found in the other analyses can be due to air as the apparatus was thoroughly evacuated before heating.

In the above analyses, no attempt was made to regulate the temperature. These first experiments were made by heating the mixture with a bunsen lamp until no more gas was given. The analysis was then made of a sample of the total amount of gas liberated. Although the reaction apparently began at a low temperature, it required a dull red heat to complete it and to change the dichromate over into chromic oxide.

That exact data might be obtained concerning the changes which take place at different temperatures, an electric heater with a thermostat was constructed. The apparatus consisted of a resistance coil packed in asbestos. This coil enclosed a double-walled mercury jacket which in turn surrounded the bulb containing the mixture of chloride and dichromate. The mercury in this jacket transmitted the heat to the bulb and at the same time, by expansion and contraction, opened and closed a shunt for regulating the temperature. The bulb was made with a neck for introducing a thermometer and a delivery tube for the gases. With this apparatus the whole bulb containing the mixture could be uniformly heated and the temperature could be easily kept within a range of two degrees. The gases were determined gravimetrically. The water formed in the reaction was collected in a phosphoric anhydride bulb and the nitrogen peroxide was taken out by a small potash bulb. In the first experiment the nitric oxide was removed by passing the gas through a piece of apparatus consisting of a sodium peroxide tube followed by a pyrogallate bulb, the latter being used for the purpose of retaining any oxygen which might be liberated by traces of moisture coming in contact with the peroxide. Later this gas was determined by absorption in a ferrous sulphate solution. The nitrogen was collected and measured over water.

The following table of weights was obtained by heating a mixture of two molecules of ammonium chloride and one molecule of potassium dichromate at a temperature of 288–290° until gas ceased to come off. This required about eight hours. Previous to heating, the whole apparatus was carefully swept out with pure nitrogen. The absorption bulbs were removed at the end of the experiment and weighed. That these data may be compared with those of Table 1, the nitrogen and the oxides of nitrogen have been converted into percentages by volume. The following is a result of three analyses:

TABLE 2.

Analysis.	I. Grams.	II Grams.	III. Grams.
Weight of mixture	7.5000	12 046	12.046
H_2O	0.6470	1.446	1.3280
NO_2	0.0127	0.0272	0.0052
NO	0.0072	lost	0.0269
N_2	0.3280	0.6000	0.4663
$Cr_2O_3.2H_2O$	.	4.520	.....
NO_2 by volume	2.26	.....	0.63
NO by volume	1.97	.....	5.08
N_2	95.77	.....	94.29

In these determinations the ammonium chloride and potassium dichromate were not all decomposed, both being found unchanged in the residue after heating at 290°. In fact, the water and nitrogen liberated were only about one-half of the amount which should have been given off, had the reaction been complete and all of ammonium chloride and dichromate decomposed.

A comparison of this table with Table 1 will show that entirely different reactions take place when the mixture is heated at 290° and at a dull red heat. This is not only evident from the composition of the gas liberated but also from the nature of the residue left after lixiviation.

Hydrated Chromic Oxide, $Cr_2O_3.2H_2O$.—No change takes place in a mixture of ammonium chloride and potassium dichromate until a temperature of 210° is reached. At this point slow decomposition begins and the mixture turns yellowish brown, due to the formation of chromium dioxide.[1] If the temperature is raised to 260° a slate-colored residue remains which, on lixiviating with water, leaves small greenish black iridescent spangles. This substance proved to be a hydrated oxide of chromium containing, however, a trace of chlorine which was very difficult to remove. Two analyses of this substance gave the following:

I. 0.5090 g. substance gave 0.0978 g. H_2O = 19.2 per cent.

II. 2.9608 g. substance gave 0.6474 g. H_2O = 21.6 per cent.

$Cr_2O_3.2H_2O$, $2H_2O = 19.15$.

The samples used in the above analyses were prepared at different times and under different conditions. The oxide used in the first analysis was dried in a vacuum desiccator, while that used in the second was dried in an air bath at 100°.

The change which takes place when a mixture of ammonium chloride and potassium dichromate is heated may be further shown from the fact that not only a change of temperature but also a change in the proportions of the salts will change the reaction. For instance, when a mixture of one part of ammonium chloride and four of the dichromate is heated to 370° a gray residue remains containing a trace of a violet substance, presumably the trichloride, as chromium chloride was found in the residue. When the above proportions were used no unchanged dichromate was found in the residue after heating. However, a strong odor of ammonia was noticed when the retort was opened.

When the proportions were reversed, using one part of ammonium chloride and four of the dichromate and the mixture heated to 370°, a black residue together with some unchanged dichromate remained. No violet compound was found.

The first change which evidently takes place on heating a mixture of ammonium chloride and potassium dichromate is the dissociation of the ammonium chloride. By diffusion, the ammonia passes up through the mixture and into the drying bulbs more rapidly than does the hydrochloric acid. There is left, then, in the mixture, free hydrochloric acid which reacts with the dichromate. By varying the temperature and the amount of hydrochloric acid, a series of reactions may take place giving all of the substances which have been found. The following may represent some of these equations:

1. $2NH_4Cl + 2HCl + 2K_2Cr_2O_7 = 4KCl + 2Cr_2O_3 + NO + NO_2 + 5H_2O$.

2. $3NH_4Cl + 2HCl + 2K_2Cr_2O_7 = 4KCl + 2Cr_2O_3 + N_2 + NO + Cl + 7H_2O$.

3. $2NH_4Cl + 4HCl + 2K_2Cr_2O_7 = 4KCl + 2Cr_2O_3 + 2NO + Cl + 6H_2O$.

---

[1] *Bull. soc. chim.*, 40, 168; *Proc. Chem. Soc.*, 24, 27.

4. $4NH_4Cl + 6HCl + 2K_2Cr_2O_7 = 4KCl + Cr_2O_3 + 2CrCl_3 + 2N + 11H_2O$.

5. $2NH_4Cl + 8HCl + 2K_2Cr_2O_7 = 4KCl + 2Cr_2O_3 + N_2 + 3Cl_2 + 8H_2O$.

At a high temperature and especially where an excess of the dichromate is used, chlorine is liberated as indicated in equations 2 and 3.

Some of the above equations are only possible, of course, when a part of the dissociated ammonia has been eliminated from the reaction as for instance by the phosphoric anhydride bulb. Any free ammonia left would react with the oxides of nitrogen and chlorine, liberating free nitrogen.

The substances above mentioned are by no means the only ones formed when the above mixtures are heated. There is formed in addition to the above substances, a small amount (representing about one per cent.) of a substance which, when brought in contact with water, liberates pure nitrogen. This substance appears to be a chromyl nitride, and is now under further investigation.

A summary of the principal facts noted above may be stated as follows:

1. The reaction between ammonium chloride and potassium dichromate when heated is not correct as ordinarily given.
2. The oxides of nitrogen are always present in the gas liberated.
3. Both ammonia and chlorine are liberated under certain conditions.
4. Other chromium compounds besides the common oxide are formed.
5. A nitride, presumably trichromyl nitride is formed.
6. The complex nature of this reaction is due in very large measure to the dissociation of ammonium chloride.

UNIVERSITY OF MINNESOTA, MINNEAPOLIS.

THE ACTION OF THIONYL AND SULPHURYL CHLORIDES ON MERCURY AND MERCURIC OXIDE.

BY H. B. NORTH.

Received December 7, 1909.

The action of sulphuryl chloride on mercuric oxide has already been studied by Spelta.[1] He states that red oxide of mercury and sulphuryl chloride do not react in the cold or even after prolonged heating in sealed glass tubes.

Yellow oxide of mercury, on the contrary, was found by Spelta to react with sulphuryl chloride when the two are heated together in sealed glass tubes at 150°. He indicates that the reaction proceeds according to the equation

$$(a) \quad 2HgO + SO_2Cl_2 = HgCl_2 + HgSO_4$$

or

$$(b) \quad HgO + SO_2Cl_2 = HgCl_2 + SO_3$$

---

[1] *Gazz. chim. ital.*, 34, 262 (1904).

depending upon the relative quantities of oxide and reagent employed.

During the course of a general research on the action of thionyl and sulphuryl chlorides on metals and metallic oxides, the author has had occasion to repeat the work of Spelta. The results, however, do not entirely concord with those obtained by the latter, as no great difficulty was experienced in causing sulphuryl chloride and red mercuric oxide to react.

Sulphuryl Chloride and Mercuric Oxide.—When *yellow* mercuric oxide and sulphuryl chloride were brought together at the ordinary temperature and pressure, reaction commenced immediately, but proceeded very slowly. After standing several days the yellow color had entirely disappeared. The white powder which remained consisted of a mixture of mercurous and mercuric chlorides.

Small quantities of the yellow oxide with an excess of sulphuryl chloride were then heated together in sealed glass tubes at a temperature of about 150°. Reaction was complete after a few hours. The solid contents of the tubes appeared in the form of clear, colorless crystals, some of which were over 1 cm. in length. When the tubes were opened, considerable pressure was noted and dense white fumes, consisting in part of sulphur trioxide, were given off.

The crystals were dried between filter papers and analyzed. Qualitative tests failed to show more than mere traces of sulphate, and this was probably due to sulphur trioxide formed in the reaction. Quantitative analysis showed the crystals to be mercuric chloride. From this it is evident that, as reported by Spelta, the reaction proceeds according to the equation "*b*" heretofore given. That no mercuric sulphate was present was of course due to the fact that a considerable excess of sulphuryl chloride was employed.

Red oxide of mercury, in contrast to the yellow compound, did not immediately react with sulphuryl chloride in the cold, but after standing several days, some reaction had taken place for the mixture was found to contain traces of both mercurous and mercuric chlorides. As previously stated, no great difficulty was encountered in causing them to react by heating in sealed glass tubes. Moreover, the temperature necessary was only 160–180°. Reaction was complete after 15 or 20 hours.

The results were the same as those obtained from the experiment with the yellow oxide. The crystals were large and clear, and when the tubes were opened dense white fumes containing sulphur trioxide were evolved. Likewise the crystals analyzed to mercuric chloride and showed a mere trace of sulphate.

Why this result differs from that obtained by Spelta is difficult to explain. It is possible, however, that the oxide used by him had been prepared at a higher temperature, in which case it would naturally show greater resistance to the action of the reagent.

Sulphuryl Chloride and Mercury.—Sulphuryl chloride was found to have no action upon metallic mercury under ordinary conditions of temperature and pressure. But when heated together in sealed glass tubes at 160–180°, reaction was complete after a few hours and a well crystallized product resulted. Great pressure was developed and much sulphur dioxide was evolved when the tubes were opened. The crystals analyzed to mercuric chloride and contained no sulphate. It is probable that the reaction is a simple one, as expressed by the following equation:

$$Hg + SO_2Cl_2 = HgCl_2 + SO_2.$$

When an excess of mercury was used, the solid product formed was noncrystalline, and consisted entirely of mercurous chloride.

Thionyl Chloride and Mercuric Oxide.—A very strong reaction resulted upon bringing thionyl chloride into contact with *yellow* mercuric oxide. Much heat was evolved and the solid contents of the tube became white. Reaction stopped after a few minutes The white mass was found to be a mixture of the two chlorides of mercury. When *red* oxide of mercury was employed, the same reaction took place, but much more slowly.

In order to obtain better products, both reactions were carried out in sealed glass tubes at about 160°. After heating several hours the tubes presented the same appearance. The crystals were large, and the supernatant liquid was clear but slightly yellowish in color.

Upon opening the tubes they were found to be under no pressure and no sulphur dioxide was evolved. The crystals were mercuric chloride and contained no sulphate. The author is of the opinion that reaction takes place with the formation of sulphuryl chloride and sulphur monochloride according to the following equation:

$$HgO + 5SOCl_2 = HgCl_2 + 3SO_2Cl_2 + S_2Cl_2.$$

The fact that no gaseous products were formed seems to substantiate this view. Furthermore, the supernatant liquid, after decomposition by water, gave a strong test for sulphuric acid. When thionyl chloride is decomposed by water the products are hydrochloric acid and sulphur dioxide.

If the above reaction is true, it can take place only when a large excess of thionyl chloride is present. To ascertain the truth of this, other tubes were prepared, care being taken to employ less of the reagent. In these tubes considerable pressure was developed due to sulphur dioxide formed. The reaction probably proceeds according to the equation

$$HgO + SOCl_2 = HgCl_2 + SO_2.$$

Thionyl Chloride and Mercury.—Thionyl chloride, like sulphuryl chloride, was found to have no reaction upon metallic mercury in the cold. But after heating in sealed glass tubes for a few hours at 150°, reaction was complete. As in the case of thionyl chloride and mercuric oxide, when a large excess of reagent was employed, no sulphur dioxide was formed and the tubes were therefore under no pressure. But when only a slight excess was employed, considerable pressure was developed. In both cases a strong odor of sulphur monochloride was noticeable while the crystals were being dried, and the filter paper was colored slightly yellow, evidently by this compound. Reaction probably proceeds according to one of the two following equations, depending upon the amount of thionyl chloride used:

$$Hg + 4SOCl_2 = HgCl_2 + 2SO_2Cl_2 + S_2Cl_2$$
$$3Hg + 4SOCl_2 = 3HgCl_2 + 2SO_2 + S_2Cl_2.$$

When an excess of mercury was employed, mercurous chloride, sulphur dioxide and sulphur monochloride were the products.

The author has heretofore investigated many reactions between thionyl chloride and metals or oxides, but the two above-mentioned reactions, in which a large excess of thionyl chloride was used, are the first he has found in which no pressure is developed or in which sulphur dioxide is not one of the final products. It has not been possible to positively identify sulphuryl chloride inasmuch as the amount of thionyl chloride used was small, and the boiling points of the two liquids are too close to allow of definite tests by fractional distillation of small quantities. However, considering the facts heretofore given, the author has little doubt that the reaction proceeds with the formation of sulphuryl chloride, according to the equations given.

The two reactions with sulphuryl chloride are also noteworthy inasmuch as they are the first reactions found for this reagent in which sulphur trioxide or a sulphate is produced.

DOES CALOMEL FURNISH ANOTHER CONTRADICTION OF THE THEORY OF HETEROGENEOUS DISSOCIATION EQUILIBRIUM?

By Alexander Smith.

Received January 4, 1910.

As is well known, undried ammonium chloride gives, at 360°, values for the vapor density corresponding to the formula ½ NH_4Cl, and indicating complete dissociation. Brereton Baker,[1] however, using the Victor Meyer and the Dumas methods found that the salt, when elaborately dried, gave at the same temperature values corresponding very nearly to the formula NH_4Cl. Since, in each case, to operate the method, about one atmosphere pressure of the vapor was necessary, it is fair to infer that in the first case the undried solid was in equilibrium with a minute partial pressure of the undissociated molecules, while in the second case the dried solid was in equilibrium with something like 760 mm. pressure of the same molecules. Abegg[1] has recently called attention to this anomaly, consisting in an apparent contradiction of the theory of heterogeneous dissociation equilibrium. At his instance, F. M. G. Johnson[2] has measured the vapor pressures of the salt, and established the fact that at about 340° the dried and undried forms of the substance do give undissociated and dissociated vapor, respectively, and yet exhibit equal pressures (amounting to 760 mm.) of the saturated vapors. The existence of the anomaly is therefore demonstrated.

---

[1] *J. Chem. Soc.*, 65, 615; 73, 475.

Now Brereton Baker[3] found likewise that dried calomel, at 445°, gave vapor densities corresponding very nearly to the formula Hg_2Cl_2 (average density, 435; theory for Hg_2Cl_2, 470). Yet, as is well known, calomel when undried gives at this temperature vapor densities corresponding to the formula HgCl (or $Hg + HgCl_2$). The purpose of this paper is to point out that calomel appears therefore to exhibit the same anomaly as does ammonium chloride. The inference is, in the case of calomel, to a very slight degree less certain of confirmation, since at 445° calomel gives a vapor pressure of about two atmospheres, and at 760 mm. the vapor is therefore only half saturated and is not in equilibrium with the solid. It seems, nevertheless, probable that, at one and the same temperature, dried calomel will be found to be in equilibrium with 760 mm. pressure of Hg_2Cl_2 molecules, although undried calomel will give the same total pressure, and only a minute partial pressure of the undissociated molecules. Experiments to ascertain whether calomel does actually exhibit this anomaly are now being made in this laboratory.

The matter is of great significance for the explanation of Abegg's anomaly. Among the suggested explanations, the two most plausible are: (1) Abegg's[4] that the heat of formation of gaseous, undissociated NH_4Cl happens to be equal to the heat of dissociation of gaseous NH_4Cl into $NH_3 + HCl$; and (2) Wegscheider's[5] that it is a case of polymorphy, and suspended transformation in the dry sample, accompanied by accidental identity of the high vapor pressure of NH_4Cl molecules from the form unstable at 360° with the vapor pressure of NH_3 and HCl molecules from the form stable at 360°. Either explanation depends on a coincidence which could not occur in precisely the same way with a different substance unless the coincidence was due to some as yet unrecognized general relation, and not to accident.

CHICAGO, December 20, 1909.

THE CONDENSATION PRODUCTS OF MELLITIC ACID WITH META-AMINO PHENOL AND THEIR BEARING ON THE RELATIONSHIP OF COLOR AND FLUORESCENCE TO CONSTITUTION.

BY OSWALD SILBERRAD AND CHARLES SMART ROY.

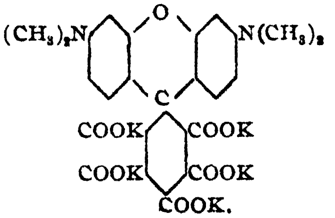
Received November 27, 1909.

In a previous paper by one of the authors on the condensation products of mellitic[1] and pyromellitic acids with resorcinol,[2] much evidence was brought to show that color and fluorescence are not necessarily dependent on quinoidal structure.

The present work deals with the corresponding rhodamines, and fully confirms the conclusions arrived at in the previous paper. Coupled with, and to some extent interdependent on these results is the possibility of ascribing fluorescence to oscillatory tautomerism. As will be shown below it is illogical and impractical to formulate all the compounds dealt with in this paper on the quinone system, and since they are without exception intensely colored and strongly fluorescent, it becomes evident that a quinoidal grouping is not a necessarily integral part of a colored and fluorescent compound.

The compounds dealt with in this paper may be divided into three groups, namely:

1. *Monoxanthyl Derivatives*, of which tetramethyldiaminoxanthylbenzenepentacarboxylic acid may be taken as typical—formula I represents the potassium salt,



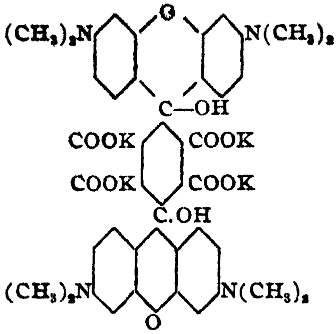
I.

2. *Dixanthyl Derivatives.*—These exist in two modifications according to whether the xanthyl groups are para or meta to one another. They behave as tetrabasic acids:

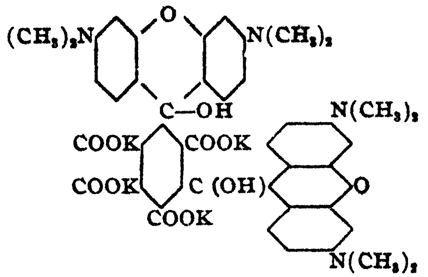
---

[1] The mellitic acid required for this investigation was manufactured from charcoal according to British Patent No. 24,662, '07.

[2] Silberrad, *J. Chem. Soc.*, 89, 1789 (1906).



II.



III.

The potassium salt of

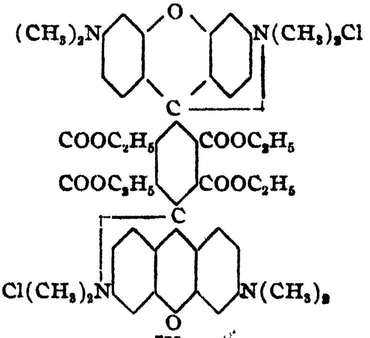
II. Octamethyltetraminodihydroxyparadixanthylbenzenetetracarboxylic acid

and of

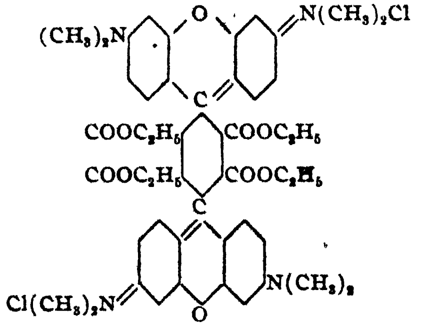
III. Octamethyltetraminodihydroxymetadixanthylbenzenetetracarboxylic acid.

3. *Trixanthyl Derivatives*, of which hydrated dodecamethylhexaminotrihydroxysymtrixanthylbenzenetricarboxylactone may be regarded as typical (formula VI). This is a well-defined base which gives rise to a readily soluble hydrochloride.

All these compounds form anisolines which may with equal readiness be formulated either as carbinol (IV) or quinone derivatives (V).



IV.



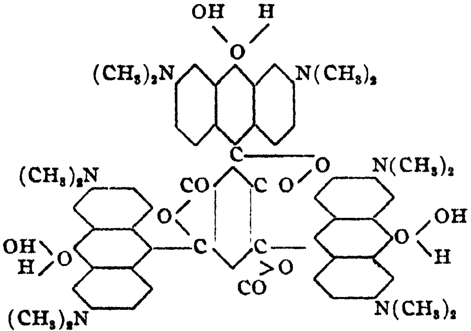
V.

Octamethyltetraminodihydroxyparadixanthylbenzenetetracarboxylic ethyl ester dichloride.

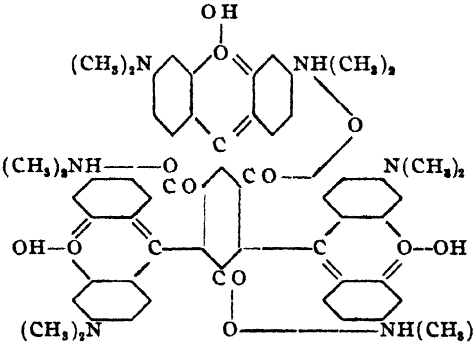
Of the two formulas, the balance of evidence is clearly in favor of a non-quinoidal structure, for there is no reason for assuming the anisolines to differ from the parent acids, the constitutions of which are fairly definitely settled below.

Constitution of the Rhodamines of Mellitic Acid.—In dealing with this subject it will be found simplest to consider the trixanthyl derivatives in the first place.

Hydrated dodecamethylhexaminotrihydroxytrixanthylbenzenetricarboxylactone may be regarded as typical. Of the many configurations it is possible to suggest on paper, we need seriously consider only two (VI and VII). The others will be found either to represent carboxylic acids, which may be rejected at once as the compound is a strong base, insoluble in caustic potash, or else, less satisfactory modifications of VI and VII.



VI.

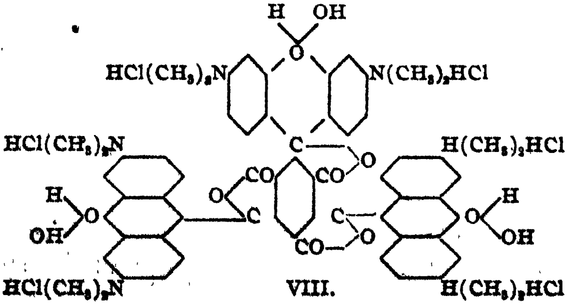


VII.

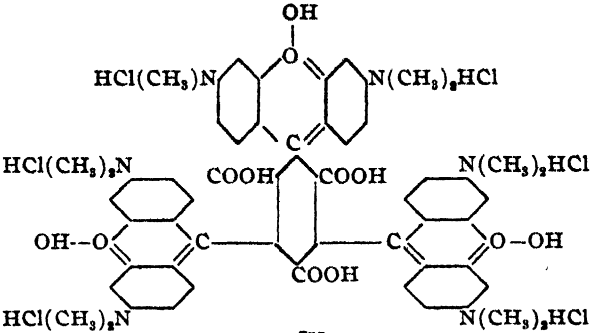
Hydrated dodecamethylhexaminotrihydroxytrixanthylbenzenetricarboxylactone.

The problem thus resolves itself into the question, Is this coloring matter a quinone or a lactone?

The compound is readily soluble in hydrochloric acid with formation of a hexahydrochloride without loss of water: formulating this salt on the two systems they assume the configurations represented by VIII and IX.



VIII.



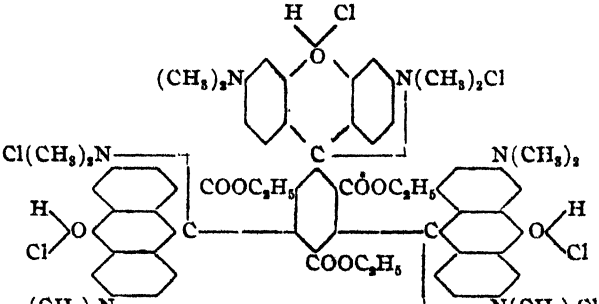
IX.

Hexahydrochloride of hydrated dodecamethylhexaminotrihydroxytrixanthylbenzenetricarboxylactone.

Of these two formula VIII is far the more probable. A free tricarboxylic acid such as represented by formula IX would scarcely form a hexahydrochloride; compare for instance the strongly acid character of the monoxanthyl derivatives which form pentabasic salts (I).

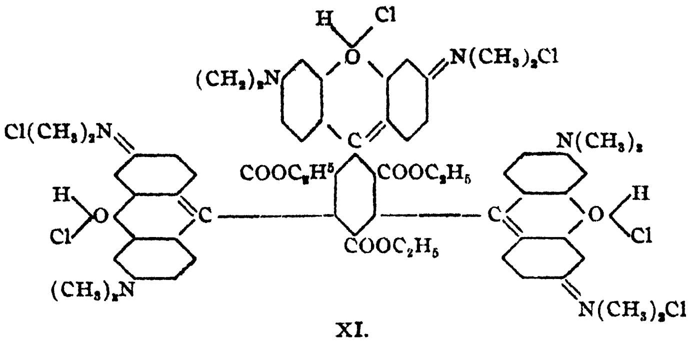
Further, anisolation can only be effected with extreme difficulty, whereas the dixanthyl derivatives, which are proved below to exist as inner salts, form anisolines with great readiness. This property must therefore be regarded as strong evidence in favor of the lactonic formula.

The anisoline chlorides combine with three molecules of hydrochloric acid forming trihydrochlorides of the trichlorides. These compounds can be formulated with equal readiness as lactones or quinones, X, XI.



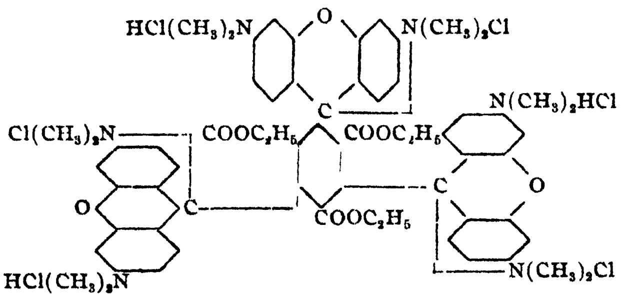
X.

Of the two formulas X is to be preferred, for although in this case the treatment required for anisolation is so drastic that the constitution may well have suffered alteration in the process, yet in the case of the dixanthyl compounds anisolation proceeds with the utmost ease: for this reason also the formula X is preferred to XII as well as to XI for the hydrochloride of the anisoline chloride; it is more strictly parallel with the most probable formula of the dixanthyl anisolines.



XI.

Trihydrochloride of anhydrododecamethylhexaminotrihydroxytrixanthylbenzenetricarboxylic ethyl ester trichloride.



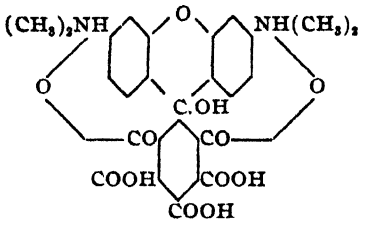
XII.

Hence this again must be regarded as an argument in favor of the lactonic formula.

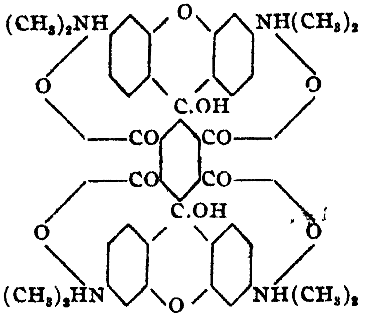
Action of Caustic Potash.—As already stated the compound is insoluble in caustic potash; heated with this reagent it slowly decomposes with evolution of dimethylamine. Such behavior is fairly conclusive evidence for the lactone formula. Indeed the possibility of an inner salt as represented by formula VII–IX withstanding the action of caustic potash in this manner is almost out of the question, especially when it is recollected that inner salts of the dixanthyl derivatives exhibit no such tendency, but dissolve immediately, forming tetrabasic salts (II and III).

It becomes evident therefore that the formula VI represents the constitution of hydrated dodecamethylhexaminotrihydroxytrixanthylbenzenetricarboxylactone, its hexahydrochloride being represented by formula VIII; while formula X most probably represents the constitution of the hydrochloride of the corresponding anisoline chloride.

Constitution of the Mono- and Dixanthyl Derivatives.—On carefully considering the properties of these derivatives in the light of the above arguments, it will become fairly evident that the parent compounds—for instance tetramethyldiaminohydroxyxanthylbenzenepentacarboxylic acid and octamethyltetraminodihydroxyparadixanthylbenzenetetracarboxylic acid—are to be regarded, not as hydrated lactones, but as inner salts, XIII and XIV.



XIII.



XIV.

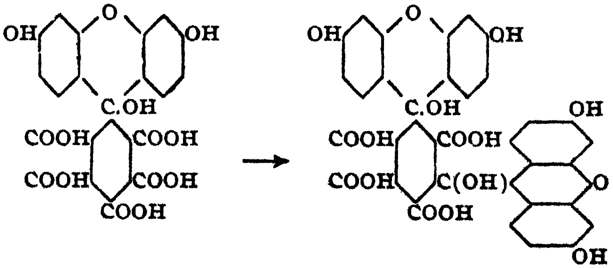
XIII. Tetramethyldiaminohydroxyxanthylbenzenepentacarboxylic acid.

XIV. Octamethyltetraminodihydroxyparadixanthylbenzenetetracarboxylic acid.

Anisolation, Action of Alkalies, Etc.—Unlike the trixanthyl derivatives these compounds anisolate with the greatest ease and dissolve at once in potash or ammonia, forming penta- and tetrabasic salts respectively (I and II). They can hardly therefore be regarded as hydrated lactones analogous to the trixanthyl compound which is insoluble in alkalies and readily dissolved in acids, but must be inner salts of true carboxylic acids.

The Formation of Dixanthyl Derivatives affords, perhaps, the most conclusive proof that the parent compounds are true inner salts.

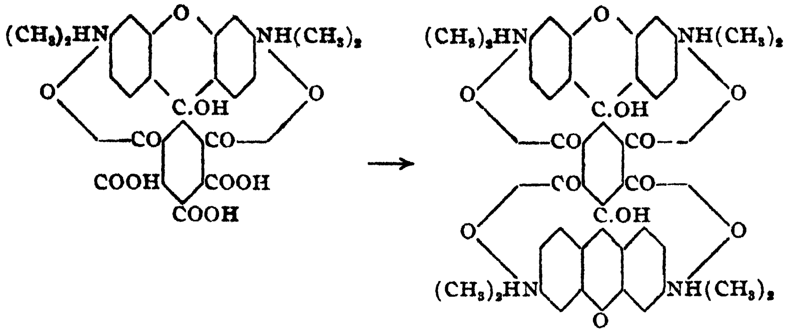
When mellitic acid is heated with four molecular proportions of resorcinol it was shown by one of the authors[1] that the monoxanthyl derivative first formed passed exclusively to the meta compound thus:



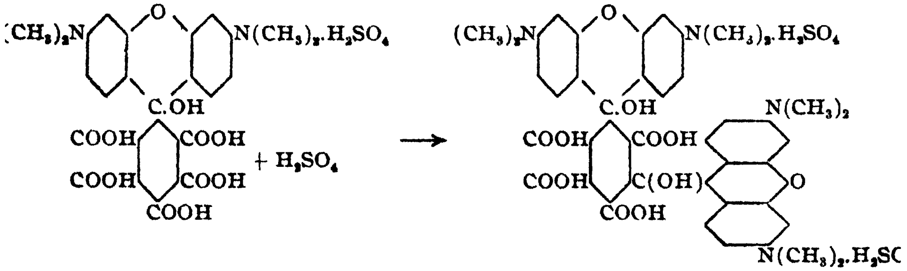
When, however, dimethylmetaaminophenol is substituted for resorcinol the para derivative is the sole product:

---

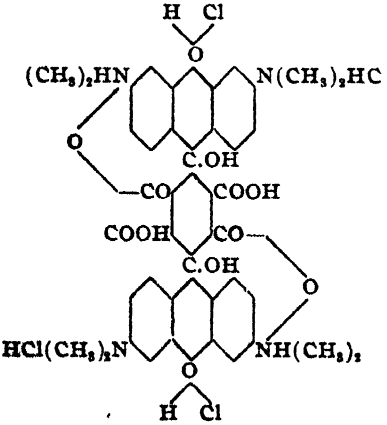
[1] *Loc cit.*



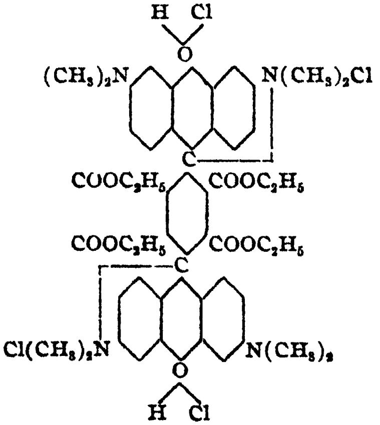
If, however, a small quantity of sulphuric acid be added the inner salt is broken up and the condensation proceeds in the normal manner with formation of the meta compound, the yield being almost theoretical:



From this it may be reasonably concluded that the parent compound exists as an inner salt.



XV.



XVI.

XV. Tetrahydrochloride of octamethyltetraminodihydroxydixanthylbenzene-tetracarboxylic acid.

XVI. Dihydrochloride of anhydro-octamethyltetraminodihydroxydixanthylbenzenetetracarboxylic ethyl ester dichloride.

The formation of a tetrahydrochloride of the acid (XV) and also the higher hydrochlorides of the anisolines (XVI) thus becomes a function of the latent property of the pyrone oxygen to become tetravalent.[1]

Lactones Isomeric but Not Tautomeric with Compounds of Quinonoid Structure.—In the previous work by one of the authors already referred to[2] indications were obtained that the lactone ring in these complex phthaleins shows much greater stability than has usually been attributed to it in compounds of this group. The present work has afforded additional evidence of this, for the trixanthyl derivatives, which must, as shown above, be regarded as lactones, are insoluble in alkalies but dissolve as lactones in acids (compare formulas VI and VIII), yielding solutions almost as strongly fluorescent as their corresponding anisolines, which, as has also been shown above, can be formulated with equal readiness either as quinonoid or carbinol derivatives (compare formulas X and XI). This has an important bearing on the theory of fluorescence of the phthalein group, which has generally been attributed to an oscillatory tautomerism between the lactone and quinonoid structures, inasmuch as it shows that no such oscillatory tautomerism can exist or account for the fluorescence of those compounds.

Orientation of the Xanthyl Groups in Aminodixanthyl Derivatives of Mellitic Acid.—As in the previous study of the resorcinol derivatives[2] the problem presented itself as to the relative positions of the xanthyl groups in the dixanthyl derivatives. As before, the method used for differentiating between the meta and the para position was to ascertain whether a third xanthyl group could be introduced.

Two isomeric dixanthyl derivatives are formed when mellitic acid is heated with dimethylmetaaminophenol, according as sulphuric acid is present or not. It is found that the compound prepared in presence of sulphuric acid is capable of taking up a third xanthyl group on heating with excess of dimethylmetaaminophenol, the resultant compound having the formula VI. Hence the dixanthyl compound from which this was prepared must have been a meta derivative, a salt of which is represented by formula III. When, however, mellitic acid and dimethylmetaaminophenol are heated together in absence of sulphuric acid, the product refuses to take up a third xanthyl group and is therefore the para compound, a salt of which is shown in formula II.

Since the para compound still contains two pairs of carboxylic groups ortho to one another, the non-formation of a trixanthyl derivative must be directly attributed to stearic hindrance, of which this thus forms one of the clearest examples on record.

Apart from this property the meta and para isomerides differ in other respects. Thus the octamethyltetraminodihydroxymetadixanthylbenzenetetracarboxylic acid is more readily anisolated than the para compound. In color also the two isomers show a marked difference.

---

[2] *Loc cit.*

Conclusions.

1. That, although it is conceivable that certain of these compounds—notably the anisolines—may possess a quinonoid structure, to represent them all as quinones, involves an absolute disregard for their properties and an indiscriminate introduction of the tetravalent oxygen irrespective of whether the presence of this element exercises a basic or acidic influence on the molecule.

2. That it may be regarded as fairly proved that *the presence of quinoidal grouping is not an essential integral part of a colored or fluorescent compound.*

Experimental Part.

In preparing the desired compounds the reacting ingredients were mixed in approximately molecular proportions and heated under widely varying conditions and the product from each experiment roughly purified and analyzed. A large quantity of the material was then prepared by that method which gave rise to the purest product. Final purification was, in most cases, effected by systematic fractional precipitation, samples being taken from time to time and analyzed; the fractionation was then again proceeded with until the analytical results became constant. In the execution of this work over four hundred analyses, the majority being nitrogen estimations, were carried out.

Monoxanthyl Derivatives.

3,6-Diamino-9-hydroxyxanthylbenzene-2-carboxylactone 3,4,5,6-Tetracarboxylic Acid (2 molecules metaaminophenol + 1 molecule mellitic acid), $C_{24}H_{14}O_{11}N_2$.

Preparation.—A finely powdered mixture of 6.84 parts mellitic acid and 4.32 parts metaaminophenol is heated to 160° for 8 hours. The resulting mass is ground and extracted with dilute aqueous caustic potash, the solution obtained filtered and the condensation product precipitated by acidification. The precipitate is filtered off, washed with boiling water, and then with alcohol, until the alcoholic washings are only slightly colored. The residue is purified by repeated fractional precipitation from an alkaline solution by the addition of dilute hydrochloric acid. The precipitate is finally boiled with a large volume of water, filtered and dried on a porous tile at 100°.

Calculated for $C_{24}H_{14}O_{11}N_2$:	N, 5.53.
Found (three different preparations):	N, 5.39, 5.55, 5.38.

Properties.—Light brown, amorphous powder, decomposing without melting above 300°. Insoluble in water, concentrated hydrochloric acid and nearly all organic solvents. Readily soluble in dilute alkalies giving a deep brown solution having a green fluorescence, precipitated from its solution on acidulation. Readily soluble in concentrated sulphuric acid, giving a brownish black solution, from which, on dilution, the acid is again precipitated. Fairly soluble in glacial acetic acid, giving a dark brown solution, from which the compound is precipitated on dilution.

Potassium Salt.—This is prepared by boiling an excess of the acid with dilute caustic potash, filtering off the excess and evaporating the neutral solution thus obtained to dryness. The salt separates out as a dark brown powder with a very dark bronzy metallic reflex; readily soluble in water, giving a deep brown solution.

Silver Salt, $C_{24}H_{10}O_{11}N_2Ag_4$.—This is precipitated as a dark brown powder on adding silver nitrate to a solution of the potassium salt. It is fairly stable to heat and light; is decomposed by dilute nitric and glacial acetic acids, the free acid being precipitated. It dissolves instantly in ammonia.

Calculated for $C_{24}H_{10}O_{11}N_2Ag_4$:	Ag, 46.25.
Found (two different preparations):	Ag, 46.35, 46.38.

The copper, barium, lead, ferrous and chromium salts form brown precipitates, while the cobalt, mercuric and ferric salts are reddish brown in color. The compound forms no definite hydrochloride.

Tetramethyl-3,6-diamino-9-hydroxyxanthylbenzenepentacarboxylic Acid (2 mols. dimethylmetaaminophenol + 1 mol. mellitic acid), $C_{28}H_{24}O_{12}N_2$.

Preparation.—A finely ground mixture of 6.2 parts mellitic acid and 5 parts dimethylmetaaminophenol is heated to 170° for 8 hours. During heating the mixture gradually solidifies, and on cooling forms a hard bronzy mass. This is powdered, boiled with water and then with alcohol to remove any unchanged acid or phenol. The condensation product is dissolved in dilute aqueous caustic potash, filtered and fractionally precipitated by the addition of hydrochloric acid. This treatment will be found insufficient to remove the impurities present. (The purest fraction from the fifteenth precipitation gave N = 5.17; $C_{28}H_{24}O_{12}N_2$ requires 4.84 per cent.) In order to obtain the pure compound, protracted extraction with alcohol followed by repeated fractional precipitation from its solution in dilute alkali by the addition of acid is necessary. In this way a pure compound is ultimately obtained.

Calculated for $C_{28}H_{24}O_{12}N_2$:	C, 57.90; H, 4.17; N, 4.84.
Found (three different preparations):	C, 57.68, 57.72; H, 4.24, 4.22; N, 4.94, 4.91, 4.95.

Properties.—Amorphous heliotrope-colored powder which decomposes, without melting, above 300°. Dyes silk and wool a silvery violet-pink. Insoluble in water, alcohol, chloroform, ether and ethyl acetate and only very slightly soluble in aniline and phenol. Slightly soluble in glacial acetic acid from which solution it is precipitated on dilution with water. Soluble in concentrated hydrochloric and sulphuric acids giving brown solutions; on dilution the pink color returns and the acid is for the most part precipitated unaltered. Readily soluble in dilute caustic potash and ammonia, giving dark red solutions having a brown fluorescence; from these solutions the compound is precipitated on acidulation.

The Potassium Salt is prepared by boiling an excess of the acid with dilute alkali, filtering off the excess and evaporating the neutral solution to dryness. The salt forms a dark violet-red powder having a dark violet reflex. It is very soluble in water and its solution fluoresces strongly.

The Silver Salt $C_{28}H_{10}O_{12}N_2Ag_5$ is precipitated as a dark blood-red precipitate, which when dry has a dark reddish brown color and is remarkably stable to light. Dissolves instantly in ammonia. Dilute nitric and glacial acetic acids dissolve the salt and precipitate out the acid.

Calculated for $C_{28}H_{10}O_{12}N_2Ag_5$: Ag, 48.43.
Found (two different preparations): Ag, 48.67, 48.59.

The copper, cobalt, ferric and ferrous salts are precipitated as reddish brown powders, while the barium and chromium salts are blood-red precipitates. The compound forms no definite hydrochloride. On evaporating its solution in concentrated hydrochloric acid the residue retains only traces of chlorine, which it slowly loses over quicklime.

Tetramethyl-3,6-diamino-9-hydroxyxanthylbenzenepentacarboxylic Ethyl Ester Chloride, $C_{38}H_{43}O_{11}N_2Cl$.

Preparation. — Tetramethyl-1,3,6-diamino-9-hydroxyxanthylbenzene pentacarboxylic acid is suspended in absolute alcohol and dry hydrochloric acid gas passed through the liquid, until nearly all the acid has gone into solution. The mixture is evaporated to dryness on the water bath and the residue extracted with alcohol. The unchanged acid is filtered off and the filtrate evaporated to dryness, and finally purified by repeated fractional precipitation.

Calculated for $C_{38}H_{43}O_{11}N_2Cl$: N, 3.79; Cl, 4.80.
Found (three different preparations): N, 3.96, 3.67, 3.65; Cl, 5.16, 4.98, 4.61.

Properties. — Dark violet-red, amorphous powder, having a bronzy metallic reflex. Dyes silk and wool a violet-red. Insoluble in ether, benzene and chloroform. Very slightly soluble in water, acetone, ethyl acetate and concentrated hydrochloric acid, giving fine deep pink solutions. Readily soluble in phenol, aniline, glacial acetic acid and alcohol in which last it gives a deep violet-red solution having an intense brown fluorescence. Readily soluble in concentrated sulphuric acid, giving a brown solution which on dilution becomes red. In strong, cold, caustic potash and ammonia it is slightly soluble, giving deep violet-red solutions having a brown fluorescence.

Hydrochloride of Tetramethyldiaminohydroxyxanthylbenzenepentacarboxylic Ethyl Ester Chloride, $C_{38}H_{44}O_{11}N_2Cl_2$.

Preparation.—On evaporating the pure anisoline chloride described above with hydrochloric acid the ester takes up another molecule of hydrochloric acid. The compound is purified by exposure over quicklime until it becomes constant in weight.

Calculated for $C_{38}H_{44}O_{11}N_2Cl_2$: Cl, 9.03.
Found: Cl, 8.5.

Properties.—Dark reddish powder possessing a bronzy reflex. On treatment with water it loses one molecule of hydrochloric acid with formation of the anisoline chloride.

Tetraethyl-3,6-diamino-9-hydroxyxanthylbenzenepentacarboxylic Acid (2 mols. diethylmetaaminophenol + 1 mol. mellitic acid), $C_{32}H_{32}O_{12}N_2$.

Preparation.—A finely ground mixture of six parts mellitic acid and 5 parts diethylmetaaminophenol is heated to 170° for 5 hours. The mass on cooling is dissolved in dilute caustic potash, filtered, and the condensation product precipitated by means of hydrochloric acid, filtered off, washed with boiling water, then with alcohol, and purified by repeated fractional precipitation of its alkaline solution by the addition of acid. The compound is then freed from salt which it tenaciously retains, by extraction with water.

Calculated for $C_{32}H_{32}O_{12}N_2$: N, 4.41.
Found (two different preparations): N, 4.48, 4.39.

Properties.—Dull red heliotrope, amorphous powder, which decomposes without melting above 300°. Dyes silk and wool a silver gray pink. In its solubility and other properties, it is practically identical with the tetramethyl compound.

Octamethyl-3,3′,6,6′-tetramino-9,9′-dihydroxy-m-dixanthylbenzene-2,4,5,6-tetracarboxylic Acid (4 mols. dimethylmetaaminophenol + 1 mol. mellitic acid), $C_{44}H_{42}O_{12}N_4$.

Preparation.—6.84 parts of mellitic acid and 11 parts dimethylmetaaminophenol are finely ground together and heated to 165–170° with 4 parts concentrated sulphuric acid for 6 hours. The mixture gradually solidifies. On cooling, the mass is ground, boiled out thoroughly with water and the residue dissolved in dilute alkali. The solution is filtered and the condensation product precipitated by means of acid. The product is then well washed with boiling water, then with alcohol to remove unchanged dimethylaminophenol, and purified by repeated fractional precipitation from its potassium salt by means of acid.

Calculated for $C_{44}H_{42}O_{12}N_4$: C, 64.50; H, 5.17; N, 6.86.
Found (three different preparations): C, 64.34, 64.42, 64.36; H, 5.16, 5.31, 5.17; N, 6.76, 6.85, 6.72.

Properties.—Bright violet-red, amorphous powder, much brighter than the para isomeride. Decomposes without melting above 300°. Dyes silk and wool a violet-red; is insoluble in water, alcohol, chloroform, ethyl acetate, ether and acetone Fairly soluble in phenol and aniline. Readily soluble in concentrated sulphuric, hydrochloric and acetic acids, from [illegible] precipitated on being largely diluted. Very soluble [illegible] and ammonia, giving a deep violet-red solution, [illegible] ence, precipitated on acidification.

[illegible] and lithium salts are dark brownish violet powders with [illegible] metallic reflex Very soluble in water, forming deep bright violet red solutions having an intense brown fluorescence.

Silver Salt, $C_{44}H_{38}O_{12}N_4Ag_4$ – Is a dark violet-red powder, with a dark violet red reflex Is extremely stable to light and heat and dissolves instantly in ammonia Dilute nitric and acetic acids dissolve the salt but precipitate out the acid

Calculated for $C_{44}H_{38}O_{12}N_4Ag_4$	Ag, 34 65
Found (two different preparations)	Ag, 34 51, 34 66

The copper, barium, cobalt, ferric, ferrous, chromium and mercuric salts are formed as bright violet red precipitates, the copper and barium salts being unaltered by ammonia.

Tetrahydrochloride of Octamethyl-3,3',6,6'-tetramino-9,9'-dihydroxymetadixanthylbenzene 2,4,5,6-tetracarboxylic Acid, $C_{44}H_{46}O_{12}N_4Cl_4$

Preparation -The aforementioned acid is dissolved in concentrated hydrochloric acid and the solution evaporated to dryness on the water bath and allowed to stand over quicklime until a constant weight is reached

Calculated for $C_{44}H_{45}O_{12}N_4Cl_4$	Cl, 14 73
Found (three different preparations)	Cl, 15 00, 14 97, 14 95.

Properties — Dark reddish powder possessing a metallic reflex, which when dissolved in water suffers hydrolysis, the acid being precipitated practically free from chlorine. Under no conditions could a compound containing two molecules of hydrochloric acid be obtained.

[illegible] *mino-9,9'-dihydroxymetadixanthylbenzene - 2,4,5-* [illegible] *er Dichloride*, $C_{52}H_{58}O_{10}N_4Cl_2$.

[illegible] oing acid is suspended in alcohol and dry hydro-[illegible] acid gas [illegible] through the mixture. The acid rapidly passes into solution with evolution of heat. In order to obtain the pure compound it is advisable to stop the current of gas just before all the acid is esterified. The mixture is then evaporated to dryness, the residue extracted with alcohol and the alcoholic extract precipitated by the addition of water.

Calculated for $C_{52}H_{56}O_{10}N_4Cl_2$:	N, 5.73; Cl, 7.27.
Found (two different preparations):	N, 5.98, 5.81; Cl, 7.27, 7 43.

Properties.—Dark violet-red amorphous powder having a bright bronzy reflex. On rapid heating it softens at 169–170°. Dyes silk and wool a reddish violet. Insoluble in ether, water, acetone, benzene, chloroform and ethyl acetate. Readily soluble in phenol, glacial acetic acid and aniline, giving bright violet-red solutions. Readily soluble in concentrated sulphuric and hydrochloric acids, giving brown solutions which turn red on dilution. Readily soluble in alcohol and precipitated therefrom on dilution with water.

Dihydrochloride of Octamethyl-3,3′,6,6′-tetraminometadixanthylbenzene-2,4,5,6-tetracarboxylic Ethyl Ester Dichloride, $C_{52}H_{58}O_{10}N_4Cl_4$.

Preparation.—An alcoholic solution of the aforementioned anisoline is saturated with hydrochloric acid, evaporated to dryness and exposed over quicklime until the weight becomes constant.

Calculated for $C_{52}H_{58}O_{10}N_4Cl_4$: Cl, 13.65.
Found (two different preparations): Cl, 13.80, 13.88.

Properties.—Dark reddish powder possessing a bronzy reflex. On treatment with water it at once loses 2 molecules of hydrochloric acid with the formation of the anisoline dichloride.

Octamethyl-3,3′,6,6′-tetramino-9,9′-dihydroxymetadixanthylbenzene-2,4,5,6 tetracarboxylic Benzyl Ester, $C_{72}H_{66}O_{12}N_4$.

Preparation.—The potassium salt of octamethyltetraminodihydroxy-*m*-dixanthylbenzene-2,4,5,6-tetracarboxylic acid is suspended in alcohol, excess of benzyl iodide added, and the mixture heated to 130° for 8 hours. The colored solution is filtered, the residue washed thoroughly with boiling absolute alcohol, and the filtrate and washings evaporated to dryness on the water bath. The ester is purified by redissolving in alcohol, evaporating to dryness, and warming to 100° *in vacuo* to remove the excess of benzyl iodide; it is then again dissolved in alcohol and fractionally precipitated by the addition of water.

Calculated for $C_{72}H_{66}O_{12}N_4$: N, 4.76.
Found (two different preparations): N, 4.89, 4.65.

Properties.—The benzyl ester is a bright reddish violet, amorphous powder, having a dark violet-red metallic reflex. On rapid heating it melts and froths up at 147°. Dyes silk and wool a fine reddish mauve color. Insoluble in water, ether, benzene, caustic potash and ammonia. Slightly soluble in ethyl acetate and chloroform. Readily soluble in alcohol, aniline, acetone, phenol, and glacial acetic acid, the last giving a deep red colored solution having an intense brown fluorescence. Readily soluble in concentrated sulphuric acid with a reddish brown coloration which turns much redder on dilution.

Octamethyl-3,3′,6,6′-tetramino-9,9′-dihydroxyparadixanthylbenzene-2,3,5,6-tetracarboxylic Acid (4 mols. dimethylmetaaminophenol + 1 mol. mellitic acid), $C_{44}H_{42}O_{12}N_4$.

Preparation.—10.25 parts mellitic acid and 19.4 parts of dimethylmetaaminophenol are finely ground together and heated to 160° for 8 hours. On commencing the heating the phenol melts but subsequently the whole gradually solidifies and the reaction is completed in about 8 hours.

When cold the mass, which has a bronzy metallic glance, is powdered and the condensation product together with the unchanged phenol is extracted with dilute aqueous caustic potash. The solution is filtered and the products are precipitated by acidifying with hydrochloric acid. The precipitate is filtered off, washed very thoroughly with boiling water, then with alcohol till the washings are scarcely colored, and finally purified by repeated fractional precipitation of its potassium salt by means of dilute acid. This it will be found is insufficient to produce a pure product, it being necessary subsequently to extract for at least 2 hours with alcohol and then dry at 80° on a porous tile.

Calculated for $C_{44}H_{42}O_{12}N_4$:	C, 64.50, H, 5.17; N, 6.86.
Found (two different preparations):	C, 64.35, 64.64; H, 5.05, 5.00; N, 6.83, 6.93.

Properties.—Dark reddish violet, amorphous powder. Decomposes without melting above 300°. Dyes silk and wool a silvery pink. Insoluble in water, alcohol, chloroform, ethyl acetate and ether. Slightly soluble in aniline, phenol, glacial acetic acid from which last solution it is precipitated on dilution with water. Very soluble in dilute alkalies, precipitated on acidification. In concentrated hydrochloric and sulphuric acids it is readily soluble without decomposition, and is precipitated on addition of water.

Salts.—The potassium and lithium salts are dark violet-red powders, having a dark violet-red reflex. They dissolve readily in water, giving fine violet-red solutions which show a marked brown fluorescence in concentrated solution.

Silver Salt, $C_{44}H_{38}O_{12}N_4Ag_4$, is precipitated as a dull red precipitate which is very stable to light and heat. It is readily soluble in ammonia. Dilute nitric and acetic acids dissolve the salt with precipitation of the free acid.

Calculated for $C_{44}H_{38}O_{12}N_4Ag_4$:	Ag, 34.65.
Found (four different preparations):	Ag, 34.67, 34.79, 34.52, 34.48.

The copper, cobalt, lead, ferrous and chromium salts are precipitated as deep red powders, while the barium salt is a blood-red precipitate.

The ferric salt is as a reddish brown, gelatinous precipitate.

Tetrahydrochloride of Octamethyl-3,3′,6,6′-tetramino-9,9′-dihydroxyparadixanthylbenzene-2,3,5,6-tetracarboxylic Acid, $C_{44}H_{40}O_{12}N_4Cl_4$.

Preparation.—A solution of the acid in strong hydrochloric acid is evaporated just to dryness on the water bath; and then exposed over quicklime until its weight becomes constant.

Calculated for $C_{44}H_{46}O_{12}N_4Cl_4$: Cl, 14.73.
Found (two different preparations): Cl, 14.51, 14.55.

Properties.—Dark reddish powder possessing a metallic reflex, which, when dissolved in water, evidently suffers hydrolysis, the acid being reprecipitated practically free from chlorine. Under no circumstances could a compound containing 2 HCl be obtained.

Octamethyl - 3,3,'6,6' - tetramino - 9,9' - dihydroxyparadixanthylbenzene - 2,3,5,6-tetracarboxylic Ethyl Ester Dichloride, $C_{52}H_{56}O_{10}N_4Cl_2$.

Preparation.—The corresponding acid is suspended in alcohol and dry hydrochloric acid gas passed slowly through the solution. During this process the temperature rises; the gas is passed through the mixture until solution is almost complete. The product is then evaporated to dryness, the residue extracted with alcohol, and the alcoholic extract evaporated on the water bath and purified by fractional precipitation.

Calculated for $C_{52}H_{56}O_{10}N_4Cl_2$: N, 5.73; Cl, 7.27.
Found (two different preparations): N, 5.62, 5.90, 5.84; Cl, 7.46, 7.52.

Properties.—Dark reddish violet, amorphous powder, having a bronzy metallic reflex. On rapid heating the substance begins to froth up at 138°. Dyes silk and wool a violet-red. Insoluble in ether, benzene, chloroform and ethyl acetate. Very slightly soluble in water and acetone. Readily soluble in phenol, aniline, glacial acetic acid and alcohol, giving deep violet-red solutions having an intense brown fluorescence. Readily soluble in concentrated sulphuric acid and hydrochloric acid, giving a brown solution from which the compound is precipitated on dilution with water.

Dihydrochloride of Octamethyl-3,3',6,6'-tetraminoparadixanthylbenzene-2,4,5,6-tetracarboxylic Ethyl Ester Dichloride, $C_{52}H_{58}O_{10}N_4Cl_4$.

Preparation.—An alcoholic solution of the corresponding anisoline is saturated with hydrochloric acid gas, evaporated to dryness and exposed over quicklime until the weight becomes constant.

Calculated for $C_{52}H_{58}O_{10}N_4Cl_4$: Cl, 13.65.
Found (two different preparations): AgCl, 13.29, 15.69.

Properties.—Dark reddish powder possessing a bronzy reflex. On treatment with water it at once loses two molecules of hydrochloric acid with formation of the anisoline dichloride.

Octaethyl - 3,3',6,6' - tetramino - 9,9' - dihydroxyparadixanthylbenzene - 2,3,5,6-tetracarboxylic Acid (4 mols. diethylmetaaminophenol + 1 mol. mellitic acid), $C_{52}H_{58}O_{12}N_4$.

Preparation.—This is prepared by heating 8 parts diethylmetaaminophenol with 6 parts mellitic acid to 160° for 6 hours. The unaltered diethylmetaaminophenol is dissolved out by means of alcohol, and the condensation product purified by repeated fractional precipitation from its potassium salt by the addition of dilute acid.

Calculated for $C_{52}H_{58}O_{12}N_4$: N, 6.03.
Found (two different preparations): N, 6.00, 6.17.

Properties.—Light violet-red, amorphous powder. Decomposes without melting above 300°. Dyes silk and wool a silvery violet-red. General properties similar to those of the octamethylparadixanthyl compound.

Tetramethyl - 3,6 - diaminotetraethyl - 3′,6′ - diamino-9,9′ - dihydroxymeta - dixanthylbenzene-2,4,5,6-tetracarboxylic Acid (2 mols. diethylmetaaminophenol + 2 mols. diethylmetaaminophenol + 1 mol. mellitic acid), $C_{48}H_{50}O_{12}N_4$,

Preparation.—This is prepared by heating a mixture of tetraethyldiaminohydroxyxanthylbenzenepentacarboxylic acid and dimethylmetaaminophenol in the proportion of 1 molecule of the former to two of the latter with sulphuric acid to 170° for 6 hours. Water is then added to the mixture and the condensation product filtered off and purified in the usual manner.

Calculated for $C_{48}H_{50}O_{12}N_4$: N, 6.42.
Found (two different preparations): N, 6 49, 6.33.

Properties.—Dark violet-red, amorphous powder decomposing above 300° without melting. Dyes silk and wool a violet-red color. In its general properties it closely resembles the octamethylmetadixanthyl compound.

Orientation of the Two Isomeric Dixanthyl Derivatives.—In order to determine the relative position of the two xanthyl groups the two octamethyl isomers were further heated with excess of dimethylmetaaminophenol to 200°. In the case of the para compound (prepared in the absence of sulphuric acid) no trixanthyl derivative was formed. The result was similar when this compound was heated for 12 hours to 170° with dimethylmetaaminophenol and concentrated sulphuric acid, 80 per cent. of the original dixanthyl compound being recovered in a pure state and the residue was proved to be free from trixanthyl derivatives. The xanthyl groups therefore occupy para positions in the compound produced by heating mellitic acid with 4 or more molecular proportions of dimethylmetaaminophenol in the absence of sulphuric acid. This, it is interesting to note, is contrary to the behavior of the hydroxyxanthyl derivatives dealt with in a previous paper (*J.Chem.Soc.(London)*, 89, 1760).

The compound above described as octamethyltetraminometadixanthylbenzenetetracarboxylic acid, produced by condensing mellitic acid with dimethylmetaminophenol in the presence of sulphuric acid, readily combines with another molecular proportion of the aminophenol with production of the trixanthyl derivatives described below.

Dodecamethyl - 3,3′,3′′,6,6′,6′′ - hexamino - 9,9′,9′′ - trihydroxy - sym - tri - xanthylbenzene-2,4,6-tricarboxylactone (6 mols. dimethylmetaaminophenol + 1 mol. mellitic acid), $C_{60}H_{60}O_{12}N_6$.

Preparation.—All early attempts to obtain this compound were fruitless owing to the fact that unlike the resorcinol compounds previously studied[1] direct heating of the mixture of aminophenol and mellitic acid leads to the production of the para dixanthyl derivatives. Thus varying excesses of aminophenol were heated with mellitic acid to temperatures ranging from 160 to 200° for times varying from 8 to 18 hours, both alone and subsequently in the presence of small quantities of sulphuric acid; in the latter instances small quantities of a trixanthyl compound were obtained which ultimately led to the following method of preparation.

Twenty-five parts mellitic acid were finely ground up with 62 parts dimethylmetaaminophenol, 100 parts concentrated sulphuric acid added and the whole gradually heated up to 180° and maintained at that temperature for 8 hours. After cooling, water is added to the black mixture and the whole warmed till the product is almost all dissolved. The solution is then filtered and the filtrate precipitated by the addition of a slight excess of alkali. The precipitate is then repeatedly washed, but, owing to the impervious and slime-like nature great difficulty is experienced in purifying the compound. At this stage, after drying at 100°, one preparation gave on analysis 8.6 per cent. N (required by $C_{60}H_{60}O_{12}N_6$ 7.95); after extraction with alcohol for several days in a Soxhlet it was found to contain 8.25 per cent. The product was therefore repeatedly boiled for several hours with large quantities of water, allowed to settle over night and the aqueous liquor decanted off. This treatment was then repeated with alcohol until the supernatant liquor is but faintly colored, after which the residue was finally filtered off and dried at 90°.

Calculated for $C_{60}H_{60}O_{12}N_6$: C, 68.18; H, 5.68; N, 7.95.
Found (three different preparations): C, 68.30, 67.95, 68.00; H, 5.53, 5.75, 5.53; N, 7.97, 7.88, 8.04, 7.97.

Properties.—Dark violet-brown, amorphous powder, which decomposes without melting above 300°. Dyes silk and wool a pale silver pink. Insoluble in water, alcohol, chloroform, acetone, ether, benzene, ethyl acetate and ammonia. Slightly soluble in glacial acetic acid, readily soluble in phenol giving a deep red solution. Readily soluble in concentrated sulphuric and hydrochloric acids, giving a brownish red solution which on dilution becomes red. The compound is insoluble in caustic potash; boiling with a 40 per cent. solution causes slight decomposition with evolution of dimethylamine.

Hexahydrochloride of Dodecamethyl-3,3′,3′′,6,6′,6′′-hexamino-9,9′9′′-trihydroxy-sym-trixanthylbenzene-2,4,6-tricarboxylactone, $C_{60}H_{66}O_{12}N_6Cl_6$.

Preparation.—The above lactone is dissolved in concentrated hydrochloric acid, and the solution evaporated to dryness on the water bath; the residue is then exposed over quicklime until a constant weight is reached.

---

[1] *Loc. cit.*

Calculated for $C_{60}H_{66}O_{12}N_6Cl_6$: Cl, 16.70.
Found (two different preparations): Cl, 16.96, 16 90, 16.34, 16.47.

Properties.—Dark bronzy powder. Soluble in water with gradual precipitation of the base; boiling accelerates the hydrolysis. The precipitated base is practically free from chlorine; the compound shows no tendency to produce a trichloride.

Dodecamethyl-3,3′,3″,6,6′,6″-hexamino-9,9′,9″-trihydroxy-sym-trixanthylbenzene-2,4,6-tricarboxylic Ethyl Ester Trichloride, $C_{66}H_{69}O_9N_6Cl_3$.

Preparation.—This is prepared by dissolving the foregoing acid in concentrated hydrochloric acid, precipitating the hydrochloride by means of absolute alcohol and then heating the finely divided hydrochloride thus obtained in a sealed tube with excess of alcoholic hydrochloric acid to 140°. The residue is filtered off and the alcoholic solution evaporated to dryness on the water bath, the residue being purified by repeated fractional precipitation of its alcoholic solution by means of water.

Calculated for $C_{66}H_{69}O_9N_6Cl_3$: N, 7.02.
Found (two different preparations): N, 7.11, 7.11.

Properties.—Dark violet-brown, amorphous powder having a dark metallic reflex. Decomposes without melting above 300°. Dyes silk and wool a pinkish mauve. Insoluble in chloroform, acetone, ether, benzene, ethyl acetate, glacial acetic acid, aqueous alkalies and water. Fairly soluble in alcohol, giving a deep red solution having a brown fluorescence. Readily soluble in phenol and aniline, giving red-brown solutions. Readily soluble in concentrated sulphuric and hydrochloric acids, giving red-brown solutions which on dilution assume a fine red; and from which the ester is precipitated by alkalies.

Trihydrochloride of Dodecamethyl-3,3′,3″,6,6′,6″-hexamino-9,9′,9″-trihydroxy-sym-trixanthylbenzene-2,4,6-tricarboxylic Ethyl Ester Trichloride, $C_{66}H_{72}O_9N_6Cl_6$.

Preparation.—An alcoholic solution of the corresponding anisoline is saturated with hydrochloric acid evaporated to dryness and exposed over quicklime until the weight becomes constant.

Calculated for $C_{66}H_{72}O_9N_6Cl_6$: Cl, 16.32.
Found (two different preparations): Cl, 16.00, 16.08.

Properties.—Dark reddish powder possessing a violet-bronzy reflex soluble in alcohol from which solution water precipitates the trichloride.

In conclusion we desire to express our gratitude to Messrs. Read Holliday & Sons of Huddersfield, England and Brooklyn, U. S. A., for permission to publish this work and also for supplying much of the *mellitic acid* required in its execution.

AND 27 CHANCERY LANE, LONDON, W. C.

THE STIMULATION OF PREMATURE RIPENING BY CHEMICAL MEANS.

BY A. E. VINSON.

Received December 3, 1909.

Artificial ripening of persimmons, dates and other fruits has been practiced for many years, but some particular substance has always been deemed essential, such as the empty *sake* barrel for persimmons or cloths moistened with vinegar for dates. Analogous to this and probably due to similar biochemical phenomena is the forcing of buds to open prematurely by what is supposed to be anesthetization, or by the application of heat as shown by Molisch.[1] The premature sprouting of newly formed tubers by stimulation with divers chemicals, which has been accomplished recently by McCallum,[2] belongs to this same general class of phenomena. Many plants[3] which contain certain glucosides and emulsin show an abnormally large exhalation of hydrocyanic acid or other substances after treatment with anesthetics and other poisonous vapors or by freezing, and this is accompanied by marked plasmolysis.

For a critical study of the influence of chemicals in initiating the premature ripening of fruits, a tree of particularly well adapted seedling dates was available. The fruits were light yellow when unripe and indicated their start to ripen by the appearance of a well-marked translucency, which increased and darkened until they became a deep chocolate-brown. The effect of over one hundred separate substances was studied on this material, either by exposing the fruits to the vapor of the volatile ones or by soaking them in solutions of the nonvolatile compounds.

The first results[4] seemed to indicate that the effect was dependent on chemical structure, since certain groups gave very marked results while others did not. Acetic acid and acetic ether were equally efficient, and five per cent. solutions of sodium or potassium acetate also gave good results. Aniline acetate vapor acted slowly but perfectly. Solutions of both benzoic and salicylic acids acted very promptly and completely. Oxalic acid gave marked results but malonic and succinic acids appeared to act much better. Citric, tartaric, and malic acids gave only imperfect results. In the first trials ordinary ether, chloroform and acetone failed, but it was found later that dates responded only to nearly saturated vapors of these reagents. Many substances which are not easily volatile acted quickly by direct contact but very slowly by their vapors. In general the more volatile the substance the quicker it acted; thus benzene and toluene acted very completely over night, but xylene, in the same time, affected only the bottom of the column of fruit above it, the effect traveling slowly upward. Oil of eucalyptus acted quite readily, while pennyroyal and cassia were very slow excepting by contact. Eugenol acted quickly by contact but its vapor was without effect even after many days' exposure. Camphor and naphthalene were not sufficiently volatile to give any result. Among the more peculiar results were those obtained with iodoform. With this substance the entire column turned uniformly, there being no difference between the fruits in actual contact and those farther away.

[4] *Science*, 30, 604 (1909).

A detailed account of the action of the various substances used, grouped according to their efficiency, is given below:

Fruits turned uniformly throughout the column over night by saturated vapors of the following:

Ether, chloroform, acetone, gasoline, carbon disulphide, benzene, toluene, allylisosulphocyanate, ethyl and methyl alcohols (a little slow, methyl alcohol acting better), ethyl acetate, ethyl butyrate, ethyl oxalate, ethyl chloride, ethyl bromide, acetyl chloride (not in excess), ethylene chloride (very efficient), methyl dichloride (very efficient), amyl formate, amyl acetate, acetic acid, propionic acid, butyric acid and acetal.

Fruits turned uniformly over night but farther ripening did not proceed normally with saturated vapors of:

Formaldehyde, acetaldehyde, formic acid, methyl acetate and ethyl formate. Possibly some of these would have been efficient in less concentration since excess probably interfered with the action of the enzymes.

Fruits ripened by contact over night, those above ripening in the next 24 to 48 hours:

Xylene, amyl alcohol, isobutyl alcohol, diacetic ester, benzyl chloride, benzoyl chloride, chloral, ethyl succinate, ethyl benzoate, cumene, cymene, geraniol, citral, coal oil, turpentine.

Fruits ripened by contact in the first few days; those above ripened only after prolonged exposure to vapor:

Mono-, di- and trichloroacetic acids, monobromoacetic acid, aniline acetate, pyridine, toluidine, oil of eucalyptus, benzaldehyde, hypnone, iodoform (by contact and by vapor ripening at the same time), terpineol.

Fruits ripened by contact only:

Aniline, phenolhydrazine, thymol, oil of cassia and oil of pennyroyal.

Fruits not affected:

Camphor, naphthalene, menthol, hydrochloric acid; blackened and destroyed by phenol; damaged but not ripened by chloral hydrate and sulphur dioxide.

Ethyl and amyl nitrite penetrate very rapidly and react chemically with the content of the tannin cells, causing it to precipitate and form insoluble tannin grains at once.[1] Due to the darkening of the fruit the effect on ripening other than the removal of astringency is difficult to follow. In smaller quantities it appears to stimulate the other ripening phenomena and very palatable fruits can be prepared by the use of nitrous esters. Ammonia in small quantities causes a general reddening of the fruits with shrinking at the basal end. The general ripening phenomena follow fairly well and after some days the fruits are edible.

The stimulation due to solutions was not so easily traced as that due to vapors. The first effect usually manifested itself by the appearance of translucent spots instead of the fruit turning as a whole. Many substances caused the skin to crack and curl badly, sometimes accompanied by ripening, sometimes not. Saturated solutions of benzoic and salicylic acids over night produced first effects very similar to those produced by vapors, while malonic, succinic and lactic acids in three per cent. solutions and the acid amides were almost equally efficient.

The following substances in solution caused all or nearly all the treated fruits to ripen:

Benzoic acid, salicylic acid, sodium benzoate, sodium salicylate, sodium acetate, potassium acetate, oxalic, malonic and succinic acids, lactic acid, acetamide, formamide, hippuric acid, cinnamic acid, hydroxylamine hydrochloride; hydrazine hydrochloride starts the process but normal ripening does not follow.

The following substances ripen from one-half to two-thirds of the fruits treated:

Tartaric, citric and malic acids, trichloroacetic acid (one-tenth per cent. solution), ammonium acetate, manganese sulphate and aniline acetate.

The following gave doubtful or negative results:

Potassium sulphate, manganese chloride, sulphanilic acid, acetanilide, phenacetine, protocatechuic acid, pyrogallol, orcinol, resorcinol and vanillin.

From the diversity of these reagents it is evident that the effects observed cannot be due to any particular chemical structure, nor do many of them react chemically with any known constituent of the date. Furthermore, after treatment over night with acetic acid vapor, an appreciable reaction for invertase could be obtained in the glycerol extract although a marked astringency was still present. From these facts and previous work on the intracellular invertase of the date,[2] including some recent observations[3] on the chemical organization of the green fruit while it retained its physical integrity, it was concluded that this apparent stimulation of ripening depended solely on the killing of the protoplasm. In broad terms any substance which will penetrate the cuticle and kill or stimulate the protoplasm, thereby releasing the previously insoluble intracellular enzymes without rendering them inactive, will bring about ripening, provided the fruits have reached a certain necessary degree of maturity.

[2] THIS JOURNAL, 30, 1005 (1908).

[3] *Plant World*, Jan., 1910.

The validity of this theory was tested by an experiment devised to accomplish the same results by purely physical means. Sprays of dates were heated in water for five and ten minutes at every five degrees between 60 and 95°. Below 60° they lost their astringency but remained very light colored like untreated fruits. Above 60° the color became darker, reaching a maximum at about 75°. At 80° the general aspect of the sprays was more uneven, and even the darkest individuals remained exceedingly astringent and very sweet. Above 80° the color of the entire sprays became very light, matching exactly the more immature individuals heated below 60°. Unlike the results obtained by treatment with chemicals, the effects of heat stimulation become plainly manifest only after the lapse of several days. The results, however, show clearly that if dates are heated sufficiently to destroy protoplasm but not enzymes, the ripening phenomena will follow quite completely, while at higher temperatures all ripening ceases.

Apsit and Gain[1] have shown that seeds lose their viability when subjected to anesthetics for a considerable length of time but their diastase and peroxydase remain active. In this case as in others, anesthesia in the accepted meaning of the word has nothing to do with the effects produced. The only connection is that certain substances, among many others, which kill or stimulate the protoplasm happen to produce anesthesia in animals.

The more immature fruits heated to 70° for ten minutes or longer darkened nicely but remained astringent. At higher temperatures even the more mature fruits remained permanently astringent while untreated immature fruits gradually lost their astringency. These facts can be explained only as the direct or indirect action of some specific enzyme that is destroyed at about 70°. Hydrazine hydrochloride interfered with the general trend of ripening but the astringency disappeared.

Commercially, many varieties of dates may be ripened rapidly after they have reached a certain degree of maturity. Before that time they do not contain sufficient dry matter to make a palatable fruit. Many varieties so ripened are fully equal to the natural product. This may be accomplished by exposing them to the vapors of a great many substances, but only a few are commercially practical, due to the bad flavors which most of them impart. Fruit of good flavor was obtained by treatment with the vapors of acetic and propionic acids, ethyl chloride, ethyl bromide, ethylene chloride, methylene chloride and chloroform, and with solutions of lactic, benzoic and salicylic acids and some other substances of more or less poisonous nature. Gasoline, benzene, esters of organic acids, ordinary ether, acetone, volatile oils and most other substances leave permanent disagreeable flavors.

---

[1] *Compt. rend.*, 149, 58 (1909).

Deglet Noor dates do not yield satisfactorily to these methods but can be made palatable and, if sufficiently mature, will yield fruit of fair quality when subjected to the judicious use of ethyl nitrite vapor. A small amount of this reagent (¼ to ½ cc. of 20 per cent. solution for every 1000 cc. of space enclosed) will finally render the tannin insoluble without discoloring the date badly or imparting any noticeable flavor.

It is anticipated that the application of these methods will prevent much of the enormous loss from souring which is experienced at present during unfavorable weather. Artificially ripened dates do not sour so readily as the fruit ripened on the tree and remain much freer from insects.

THE ACIDS OF THE PHENYLPROPIOLIC SERIES AND THEIR CONDENSATION TO NAPHTHALENE DERIVATIVES.[1]

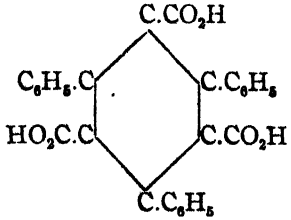
BY JOHN E BUCHER.

Received December 9, 1909

In an investigation of the action of acetic anhydride on acids of the acetylene series in 1895, Michael and Bucher[2] obtained the anhydride of a new acid from phenylpropiolic acid. Three years later,[3] after a thorough study of the compound, they proved it to be the anhydride of 1-phenyl-2,3-naphthalenedicarboxylic acid It was found to have the composition corresponding to the formula $C_{18}H_{10}O_3$ and a molecular weight of 274.

This corresponds to the composition of a phenylpropiolic anhydride $(C_6H_5C \quad C.CO)_2O$, but the acid obtained from it was found to be saturated and entirely different from phenylpropiolic acid. This structural formula evidently does not represent its constitution.

It seemed probable that three molecules of the acid might have polymerized to triphenyltrimesic acid in a manner analogous to the for-



---

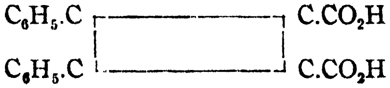
[3] *Am. Chem. J.*, 20, 89 (1898).

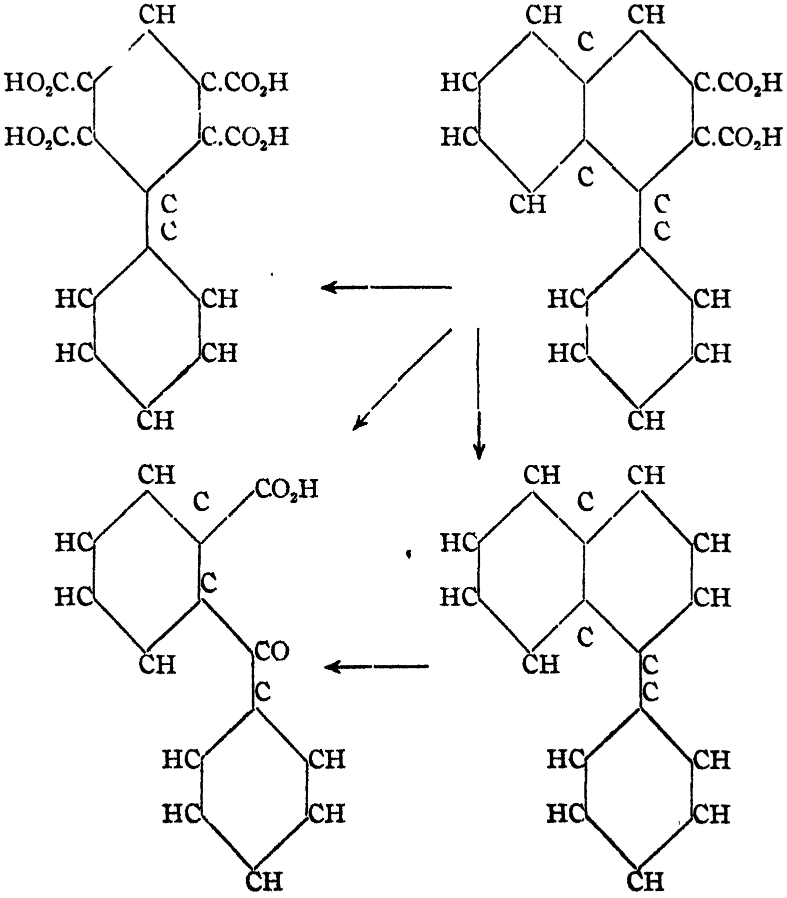
mation of benzene from acetylene. The resulting acid was found to be dibasic and to have only two-thirds of the required molecular weight. These facts showed conclusively that the compound is not the anhydride of triphenyltrimesic acid.

It was then thought possible that the compound might be the anhydride of diphenyltetrenedicarboxylic acid.



This acid would contain two carboxyl groups in the ortho position and it would be dibasic. One might expect benzil among the oxidation products of such an acid but many experiments failed to show the slightest trace of this substance. It was not possible to find any evidence in favor of the tetrene formula.

As none of these three formulas corresponded to the compound, it was evident that the polymerization of the phenylpropiolic acid must have proceeded in a very unusual manner.



They finally succeeded in isolating diphenyltetracarboxylic- and orthobenzoylbenzoic acids from its oxidation products and in preparing its hydrocarbon. The hydrocarbon was also oxidized to orthobenzoylbenzoic acid. The preceding formulas show these transformations.

These facts can only be explained by the above constitutional formula and the compound is therefore the anhydride of 1-phenyl-2,3-naphthalenedicarboxylic acid.

Later, several investigators who evidently had overlooked the above work obtained this compound. Basing their reasoning on insufficient experimental evidence, they described the substance first as the anhydride of triphenyltrimesic acid and afterwards as that of diphenyltetrenedicarboxylic acid, representing structural formulas which had already been shown to be untenable by Michael and Bucher. For example, Lanser[1] obtained the compound by heating phenylpropiolic acid with phosphorus oxychloride, and assigned the formula $C_{54}H_{30}O_9$ for triphenyltrimesic anhydride without making molecular weight determinations.

A little later Manthey[2] determined the molecular weight thus showing the formula to be $C_{18}H_{10}O_3$ and that the constitution must be different from that assigned by Lanser. This evidence together with the fact that the acid contains the two carboxyl groups in the ortho-position, led him to assign the tetrene formula.

In a later paper, Lanser and Halvorsen[3] acknowledge the correctness of Manthey's experimental work and they also accept the tetrene formula. The reactions which they study would, however, apply equally well to other ortho-dibasic acids.

Ruhemann and Meriman[4] also obtained the anhydride in studying the action of phenylpropiolyl chloride on acetone in pyridine solution. They proved the identity of their compound with that of Lanser and regarded it as a terene compound as they did not investigate its constitution.

Michael[5] next showed that the compound described by these investigators is 1-phenyl-2,3-naphthalenedicarboxylic anhydride. He proved this by preparing a specimen by Lanser's method and finding it identical in every respect with a specimen prepared by the method of Michael and Bucher.

Recently, Stobbe[6] obtained this anhydride by the action of light on dibenzalsuccinic anhydride. Failing to get diphenyltetracarboxylic acid by direct oxidation but obtaining ortho-benzoylbenzoic acid, he claimed to have shown the truth of the naphthalene formula of Michael and Bucher for the first time.

These investigators[7] showed that his failure to get the diphenyltetracarboxylic acid was due to incomplete oxidation[8] and that they had noticed the formation of ortho-benzoylbenzoic acid by the *direct* oxidation[1] of the anhydride as well as from the hydrocarbon.

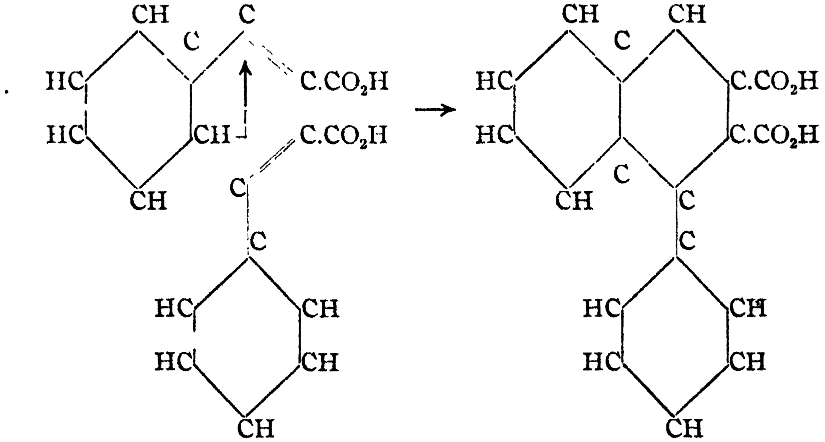
Pfeiffer and Möller[2] have polymerized phenylpropiolic ester to the ester of 1-phenyl-2,3-naphthalenedicarboxylic acid by simply heating to 200°. They point out that aromatic acetylene derivatives may thus be polymerized to naphthalene derivatives without the use of condensing agents. The earlier work of Lanser also shows this since Michael has shown that the so-called triphenyltrimesic acid is really a naphthalene derivative. Lanser obtained the anhydride of this acid by heating phenylpropiolic acid to a temperature above 200°. Pfeiffer and Möller's work, however, illustrates the additional fact thatanhydride form ation is not essential for this naphthalene condensation.

I have confirmed Lanser's experiment and have been able to get a much better yield of the ester of the naphthalene acid than Pfeiffer and Moller got. In my experiment, however, the phenylpropiolic ester was polymerized by heating it with acetic anhydride instead of heating it alone.

These investigations show that phenyl propiolic acid and its ester or chloride can be polymerized in a number of different ways to naphthalene derivatives but that the original method of Michael and Bucher which gives a quantitative yield is still the best. The following formulas indicate how this change takes place:



This work has been continued in this laboratory for a number of years in order to determine whether this transformation is general or not. Besides phenylpropiolic acid, eleven of its substitution products have been examined thus far and in every case they polymerized, on heating with acetic anhydride, to derivatives of 1-phenyl-2,3-naphthalenedicarboxylic anhydride. The facts thus far obtained justify the statement[3] that *phenylpropiolic acid and its substitution products show a strong tendency to polymerize, with the wandering of an ortho hydrogen atom, to phenylnaphthalene derivatives.*

[2] *Ber.*, 40, 3839 (1907).

[3] THIS JOURNAL, 30, 1262 (1908).

In fact, this kind of polymerization is the only form which has been thus far obtained from aromatic propiolic acids.

In this work much time was spent in preparing the aromatic propiolic acids as it was usually necessary to either prepare new compounds or else to improve the methods of preparation of acids which were already known. In most cases methods were found by which these interesting acids could be prepared readily from comparatively inexpensive materials —providing that suitable precautions were observed.

Phenylpropiolic acid was prepared in the usual way from cinnamic acid by making cinnamic ester dibromide. It is well known that alcoholic potash converts this into a mixture of the salts of allo-bromocinnamic acid and bromocinnamic acid and that the latter is easily converted into phenylpropiolic acid by the loss of hydrobromic acid. The former acid is so stable, however, that it is not practicable to convert it into phenylpropiolic acid directly by further heating with alcoholic potash. It can, however, be converted into the isomeric acid by simply heating it. This acid can then be converted, in turn, into phenylpropiolic acid. This change of the labile bromo acids into the corresponding isomeric acids was found to be quantitative in several cases. In the case of the allo-bromocinnamic acid it was noticed that when it was heated with acetic anhydride to 100° its own anhydride was produced but at a higher temperature this was transformed into the bromocinnamic anhydride. The latter could then be transformed into phenylpropiolic acid. From this, it is evident that it is not necessary to use pure phenylpropiolic acid in this work. It generally seemed desirable, however, to separate the acids first. A very good way of doing this is to crystallize them from carbon disulphide or from carbon tetrachloride. In this way it is possible to separate much of the phenylpropiolic acid from the more soluble allo-bromocinnamic acid.

In some other cases, the potassium salts of the propiolic acids were found to be very sparingly soluble in the alcoholic potash, thus yielding the pure acids at once. In all cases the potassium salts of the labile bromocinnamic acids were found quite soluble while the ammonium salts of the isomeric acids were very sparingly soluble. These properties were found very useful in separating the resulting phenylpropiolic acids from these labile substituted bromocinnamic acids which were formed.

The meta- and para-nitrophenylpropiolic acids can be prepared from the corresponding nitrobenzoic aldehydes by Perkin's synthesis. In some other cases Claissen's synthesis was found preferable to that of Perkin.

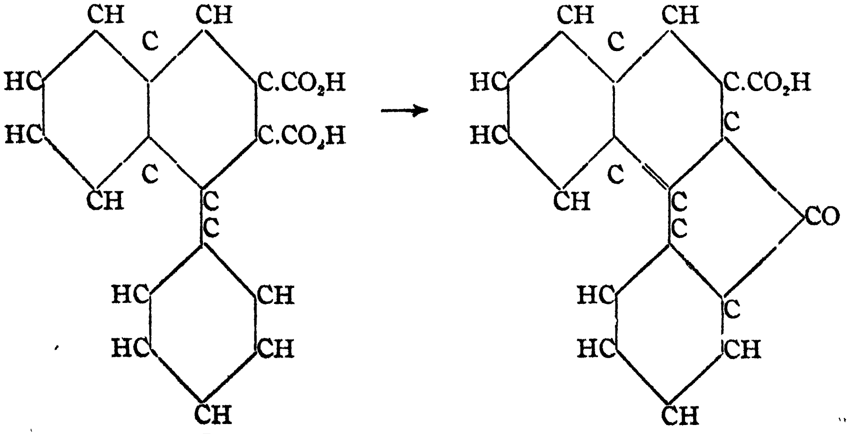
It was also found that the ortho- and para-nitrophenylpropiolic acids could be converted into the corresponding halogen acids by means of the diazo reaction.

Besides phenylpropiolic acid, the following substitution products were prepared: Piperonylpropiolic acid, *o*-chloro-, *o*-bromo-, *m*-nitro-, *m*-chloro-, *p*-nitro-, *p*-chloro-, *p*-bromo-, *p*-iodo-, *p*-methoxy-, and *p*-methylphenylpropiolic acids. These all polymerize readily to derivatives of 1-phenyl-2,3-naphthalenedicarboxylic anhydride when they are heated with acetic anhydride. In the earlier work it was found very difficult to prove this constitution for these products. The method used in case of the first compound has already been described. The meta- and para-nitro compounds were oxidized and then converted into diphenyltetracarboxylic acid thus showing them to be naphthalene derivatives. By means of the diazo reaction, they were then converted into the halogen derivatives identical with those obtained by direct polymerization. This showed the latter to have the same constitution. The constitution of the product from the para-methylphenylpropiolic acid was established by oxidizing it to a diphenylpentacarboxylic acid. In more recent work the very efficient method of oxidizing to benzenepentacarboxylic acid described below was used. By means of this method, which depends on the catalytic action of manganese nitrate in fuming nitric acid, eleven of these acids were oxidized to benzenepentacarboxylic acids, thus confirming the naphthalene constitution which had previously been assigned for some of the substances.

The following description gives an idea of some of the transformations which these substances undergo: They are all ortho-dibasic acids from which water splits out easily on heating. In fact, the first acid obtained is partially converted into its anhydride even on crystallizing it from only moderately heated glacial acetic acid. In this way, I obtained eight grams of the anhydride from twenty grams of the acid. This loss of water in crystallizing the acid from hot solvents led to the statement, made in the first description, that the acid passed into the anhydride spontaneously. This statement was corrected in a later paper by Michael. All of these acids have this general property and some of them, as well as their oxidation products, may show properties similar to those noticed by Orndorff in the case of tetrachlorophthalic acid.

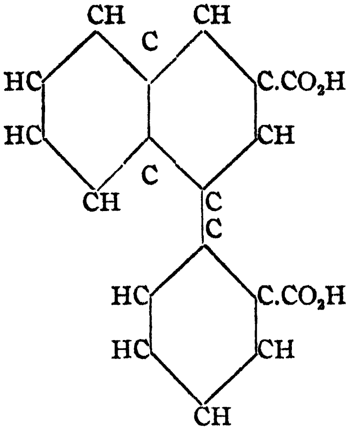
The acids all necessarily contain a carboxyl group with both ortho positions substituted. According to V. Meyer's observations one might expect difficulty in esterifying these acids. This was found to be the case, little or no neutral ester being found, on heating the substances with alcohol and sulphuric acid under the usual conditions. If more sulphuric acid is used and the heating continued for a longer time from 40 to 60 per cent. of neutral ester may be obtained.

Sulphuric acid converts the 1-phenyl-2,3-naphthalenedicarboxylic acid into red allo-chrysoketonecarboxylic acid.



I. II.

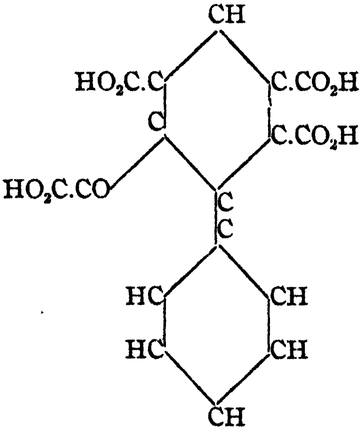
When this red acid is heated to 218° with potassium hydroxide, it is changed practically quantitatively into a new 1-phenylnaphthalenedicarboxylic acid.

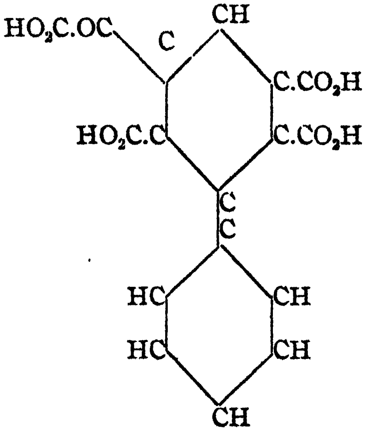


III.

Formulas I, II and III show a method of transferring a carboxyl group from the ortho position on one ring to the corresponding position on the other ring. When the new acid (III) is heated with sulphuric acid, a new red acid different from the allochrysoketonecarboxylic acid (II) is obtained.

The oxidation of these naphthalene acids in alkaline potassium permanganate solution has already been described. The yield of diphenyltetracarboxylic acid is usually small, since the intermediate ketonic acids are very stable towards alkaline potassium permanganate.

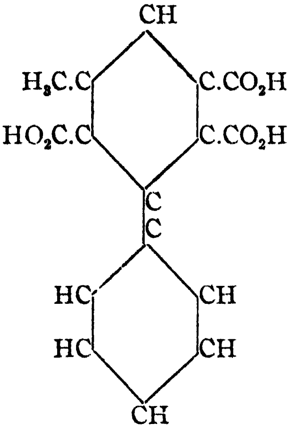




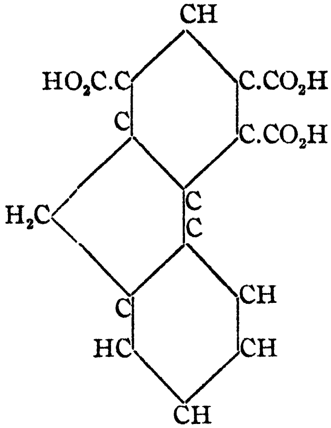
IV. V.

These ketonic acids are very easily oxidized to diphenyltetracarboxylic acids when the solution is acidified. Formulae I, IV, V and VIII indicate these reactions. These acids are obtained in the form of sirup-like solutions and they resemble phthalonic acid closely. Heated with caustic alkalies, they yield diphenyltricarboxylic acids and oxalic acid.

On reduction with hydriodic acid, the *meta*-glyoxylic acid (V) first yields methyldiphenyltricarboxylic acid (VI) which then reduces at a higher temperature to a methylfluorenecarboxylic acid. The isomeric *ortho*-glyoxylic acid (IV), even at the boiling point of hydriodic acid, reduces to a fluorenetricarboxylic acid (VII).



VI.



VII.

This shows the ease with which diphenylcarboxylic acids close the ring to form fluorene derivatives. The same tendency is shown by the action of sulphuric acid on diphenyltetracarboxylic acid (VIII) in forming the yellow diphenyleneketonetricarboxylic acid (IX), which can be reduced to the acid represented by formula VII. I have found this closing of the ring on heating to 100° with sulphuric acid, to take place when all the carboxyl groups were on the same ring but generally not when the carboxyl groups were on different rings. In diphenyleneketonecarboxylic acids of the general form IX, the ring is broken in such a way, on heating with potassium hydroxide, that the carboxyl group is transferred from the ortho position on one ring to the corresponding ortho position on the other.[1] In this case, about 299 parts out of 300 are changed in this way—making the process practically quantitative. The following formulas show these changes.

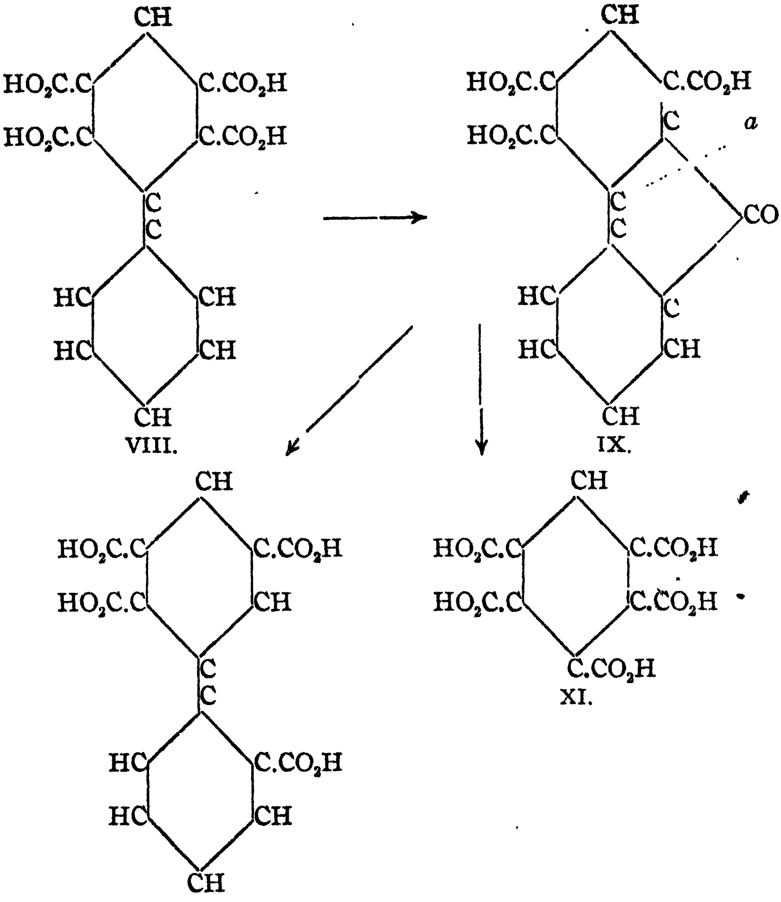
The very sharp breaking of the ring at *a* in formula IX and in the similar case of the red acid (II) indicates a tendency to remove the carboxyl groups as far as possible from each other and suggests the possibility of its giving a means of testing the constitution of the resulting acid. For example Bamberger and Hooker,[2] after heating a yellow diphenyleneketonedicarboxylic acid from retene with caustic alkali, represent the resulting white diphenylenetricarboxylic acid as having the three carboxyl groups on the same ring. This seemed scarcely possible in view of the above facts and an examination showed the acid to have a different structure.

The yellow diphenyleneketonetricarboxylic acid (IX) also furnishes a means of oxidizing these 1-phenyl-2,3-naphthalenedicarboxylic acids or diphenylpolycarboxylic acids (like I and VIII) to benzenepentacar-

---

[1] This Journal, 30, 1261 (1908).

[2] *Ann.*, 229, 159 (1885).



boxylic acids. The latter acid (VIII) is very stable towards alkaline potassium permanganate as on heating for six weeks I recovered 28 per cent. of unchanged acid and could not isolate any benzenepentacarboxylic acid. The yellow acid (IX), however, decolorized the theoretical quantity of permanganate in less than two hours. The very soluble acid product was not completely oxidized but it yielded benzene for the hydrocarbon. Many experiments were made in attempting to complete the reaction but without success. Even heating on the water bath with fuming nitric acid did not aid very much. A small quantity of manganese nitrate was then added to the hot nitric acid. *Brisk effervescence began at once and in a few moments pure benzenepentacarboxylic acid separated from the liquid.* The yield in this experiment was about 90 per cent. of the theory. The manganese nitrate is evidently a very efficient catalytic agent in this case. This method was also applied to the acids without first converting them into ketone derivatives, and, in eleven cases out of the twelve tested, benzenepentacarboxylic acid was found. Not only does this give a very powerful method for determining constitution but it gives a very easy method of preparing the hitherto almost inaccessible benzenepentacarboxylic acid. It also serves for the preparation of other benzene polycarboxylic acids. Bamberger and Hooker's diphenyleneketonedicarboxylic acid from retene can be oxidized in a few hours to two isomeric *benzenetricarboxylic* acids, thus showing that the constitution given for retene and all its derivatives is incorrect.

The above work dealing with the action of acetic anhydride led to the supposition that anhydrides[1] might be prepared from *meta-* and *para*-phthalic acids and their substitution products. On trying the experiment it was found that such anhydrides could be obtained quantitatively by heating a solution of the acid in acetic anhydride to 200° until the excess of reagent was distilled off. These products apparently have a very high molecular weight. A preliminary determination, in nitrobenzene by the boiling point method, for the anhydride from chloroterephthalic acid, $[C_6H_3Cl(CO)_2O]_x$, indicates that it may be as high as 1500 or 2000.

A part of this work has been carried on with the aid of my students and I wish especially to acknowledge the valuable assistance of G. F. Parmenter, N. A. Dubois, V. S. Babasinian, M. L. Dolt, W. C. Slade and F. Keyes.

The more important results of this work thus far are as follows:

1. Satisfactory methods for the preparation of a number of aromatic propiolic acids.
2. The polymerization of these acids to derivatives of 1-phenyl-2,3-naphthalenedicarboxylic acids—giving a quantitative method of synthesis.
3. Syntheses of acids of the diphenyl, fluorene and diphenyleneketone series and a study of their characteristic reactions.
4. Syntheses of benzenepentacarboxylic acid and other benzenepolycarboxylic acids.
5. The determination of the constitution of retene and its derivatives.
6. The preparation of anhydrides from meta- and para-phthalic acids and their substitution products.

BROWN UNIVERSITY, PROVIDENCE, R. I.

CATALYSIS ON THE BASIS OF WORK WITH IMIDO ESTERS.[2]

BY JULIUS STIEGLITZ.

Received December 2, 1909.

I shall not attempt to discuss to-day the general subject of catalysis but shall use the short time rather to present briefly some results[3] in certain lines of our work which seem to shed some light on three fundamental points of interest in catalysis, namely, on the questions how in certain cases a catalytic agent does its work, why it does it, and what limitations there are to its action.

---

[1] THIS JOURNAL, 30, 1263 (1908) and 31, 1319 (1909).

[2] Presented at the Second Decennial Celebration of Clark University, Worcester, Mass., September 15, 1909.

[3] Certain parts of the work are still being carried out—as indicated below—and for such parts this report is preliminary to a final one. Complete discussion of the several parts lay outside the limits of this paper and will be brought in later special reports.

It may be recalled that an imido ester, such as methyl imido benzoate, is very slowly decomposed by pure water. One of the decompositions it undergoes under these conditions is into ammonia and methyl benzoate[1] as expressed in the equation

$$C_6H_5C(: NH)OCH_3 + H_2O \longrightarrow C_6H_5CO_2CH_3 + NH_3. \quad (1)$$

The addition of an acid, say hydrochloric acid, enormously accelerates this otherwise extremely slow action and we were able to show that the acceleration is due to the fact that the reacting component in this decomposition is the positive ion of the ester,[2] as expressed in the equation.

$$C_6H_5(: NH_2{}^+)OCH_3 + H_2O \longrightarrow C_6H_5CO_2CH_3 + NH_4{}^+. \quad (2)$$

In arriving at this conclusion, account had to be taken of the so-called "salt-effect" or "salt-acceleration" produced by the presence of electrolytes, entirely analogous to the "salt-effect" in other decompositions in which water is a reacting component, as in the catalysis of esters by acids. This salt-effect being allowed for, the velocity of decomposition of an imido ester by water in the presence of acids is given in the equation[3]

$$dx/dt = K_{v(ion)} \times C_{pos.\ est.\ ion} \times [C_H \times C_{OH}]. \quad (3)$$

I have not time more than to mention the fact that it was shown that the same fundamental equation may be applied to the saponification of ordinary esters under the influence of acids, the main difference being that for such exceedingly weak oxonium bases as esters are the concentration of the positive ester ion is practically proportional to the concentrations of the ester and the hydrogen ion present at any moment, so that we may transform (3) into[4]

$$dx/dt = K_v \times C_{ester} \times C_H \times [C_H \times C_{OH}] \quad (4)$$

which is also the equation based on experience.

The work on which the above conclusions were based was carried out wholly with the hydrochlorides of the imido esters. More recently we have also carried out measurements with the hydrobromides and nitrates, and begun work also with sulphates; if the positive *ion* is the reacting component, then, determining rigorously the degree of ionization and making rigorous allowance for the salt-effect, we should find that the velocity constant for the decomposition of the positive ion in the chloride solution should also satisfy the observed rates of decomposition of these other salts. For the rigorous treatment, the "salt-effect" produced by the chlorides, bromides, nitrates, etc., has to be determined experimentally and this has been carried out[5] with the chlorides and bromides,[6] mixtures with varying amounts of the potassium and sodium salts being examined, the degrees of ionization of each salt in the mixture being determined with the aid of the principle of isohydric solutions, which was proved to apply to such mixtures.[1] The salt-effect is, except for minute quantities of salt, proportional to its concentration or rather, more probably, only to the concentration of the ionized part of the salt. The salt-effect is an acceleration and if we call $K_{v(ion)o}$ the velocity of decomposition of the imido ester ion in the absence of any salt at all, this velocity will be increased proportionally to some specific acceleration factor A, and to the concentration $m\alpha$ of the ionized part of A salt. So we have

[3] $C_{pos.\ est.\ ion}$ is a function of x.

[4] C_{ester} is a function of x.

[5] W. W. Hickman, Dissertation, 1909.

[6] Mr. Weatherby is completing the work begun by Mr. Hickman on the nitrates and sulphates.

$$K_{v(ion)obs.} = K_{v(ion)o}\,(1 + A\,m\,\alpha). \qquad (5)$$

$K_{v(ion)obs.}$ is the constant calculated according to equation (3) from the observations without any allowance for a salt-effect.

$K_{v(ion)o}$, the velocity constant when the salt effect is eliminated, is easily found by extrapolation from the observations when imido ester salts are present without added salts, A from the results obtained when salts have been added. We arrived thus empirically at the rather unexpected result that the accelerating factor A is approximately the same for sodium, potassium and lithium chlorides and for the bromides as well as for the chlorides, *viz.*, about 185 per cent. per gram molecule of fully ionized salt. Table I illustrates this fact for potassium chloride and potassium bromide. K_v is the velocity coefficient calculated without regard to the degree of ionization of the imido ester salt, α is the degree of ionization of the salt calculated with the aid of the principle of isohydric solutions. In the columns headed "found" are given the values obtained for K_v/α by experiment; in the columns headed "calculated" are the values obtained according to equation (5), in which the velocity coefficient $K_{v(ion)o}$ in the absence of any salts at all is taken as 164 and the salt acceleration factor A is taken as 185 per cent. for both series.

TABLE I.[2]

K Hal.	KCl. 43430 K_v/α.		KBr. 43430K_v/α.	
m.	Found.	Calculated.	Found.	Calculated.
0	176	176	176	177
0.1	191	190	191	190
0.2	213	214	209	215
0.25	227	226	230	227
0.333	247	245	(268)	247

I wish to emphasize this result because the work of others, notably of Arrhenius and Euler, with cane-sugar and esters, shows varying specific accelerating factors for these salts. I believe our work has the advantage of our knowing from conductivity measurements the degrees of ionization of the imido ester salts as well as of the added electrolyte so that there seems to be no unknown factor left in our estimations. But we are simply presenting these results for the time being as an empirical contribution to the whole question of catalysis and we do not consider the very complex question of "salt catalysis" as at all settled.[3]

---

[1] Edith E. Barnard, Dissertation, 1907.

[2] Taken from W. W. Hickman's dissertation.

[3] Work on "salt catalysis" is being continued by L. S. Weatherby, preliminary results by Mr. Hickman on the effect of sulphates indicated an abnormally high effect.

With the aid of the determination of the salt factor for chlorides and bromides we have been able to show that the positive ester ion shows indeed the same rate of decomposition irrespective of its origin from either of these salts and very probably also for the nitrate[1] (see the values for $K_{v/\alpha}$ for the three salts in equi-molar concentrations as given in Table II). This is exactly what our theory would require, namely, that the simple reason why the addition of an acid accelerates this decomposition is that it forms a salt whose positive ion is the reacting component and that the concentration of the ion is enormously increased when the catalyzing acid is added to the free ester, which is a very weak and therefore little ionized base.

TABLE II.[2]—ETHYL IMIDO BENZOATE.

It was suggested by Arrhenius and emphasized by Euler that the salt acceleration is probably largely due to the increased ionization of water in the presence of electrolytes, but quantitative evidence in support of such a conclusion has not been brought, as far as I am aware. In view of the increase observed by Arrhenius and others[5] in the strength of other acids in the presence of added foreign salts, *e. g.*, of acetic, formic and carbonic acids in the presence of sodium chloride, it seems a sufficiently rational assumption that water should show a similar increased ionization.[6] The imido esters, enabling us to measure the actual concentration of the reacting imido ester ion, gave us an opportunity to bring experimental evidence strongly supporting this view. From equation (3) it is obvious that if the salt acceleration is due to the increased ionization of water, *viz.*, an increase in the value of the third factor, $(C_H \times C_{OH})$ then, $C_{pos.\ est\ ion}$ being known by experiment, the velocity constant $K_{v(ion)}$ calculated *without* taking any increased value of $[C_H \times C_{OH}]$ into account, should increase in the same proportion for all the imido esters for the same concentration of added salt ions, irrespective of the fact that, according to the ester used, the decomposition may be a comparatively slow or a very fast one. We have found this to be true[7]—all the esters used show the same acceleration per gram molecule ionized salt—*i. e.*, close to 185 per cent. per gram molecule ionized potassium chloride, etc.[8]

Having found that the reacting component in these and a number of other actions under the influence of acids is the positive ion of a salt formed with the acid, we were naturally most interested in the question

---

[1] The salt effect for nitrates is now being determined.

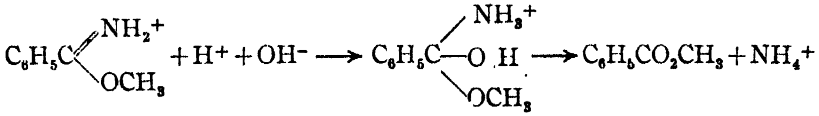
[7] Dissertation of Edith E. Barnard and W. W. Hickman.

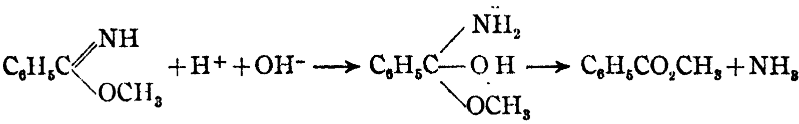
[8] The investigation of the ionization of water in salt solutions is being continued with other substances and by other methods.

why the *ion* should be so reactive, why it should be so important a component. We can hardly consider the decompositions to be *purely* ionic reactions,[1] comparable with the hydrolysis of salts in aqueous solutions, as was mistakenly assumed, for instance, by Euler and by Kastle. Such assumptions run counter to the law of mass action applied rigorously in the analysis of the conditions.[1] The law is, however, in agreement with the assumption[2] based on experience gained in organic chemistry that the following are the stages for the action:



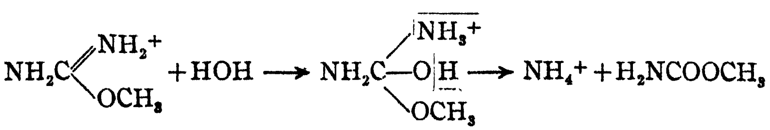
$$C_6H_5C\begin{smallmatrix}\diagup NH_2^+\\ \diagdown OCH_3\end{smallmatrix} + H^+ + OH^- \longrightarrow C_6H_5C\begin{smallmatrix}\diagup NH_3^+\\ -O\,H\\ \diagdown OCH_3\end{smallmatrix} \longrightarrow C_6H_5CO_2CH_3 + NH_4^+ \qquad (6)$$

Now, we may well ask why this should be an enormously faster action than the entirely analogous possible action of water on the non-ionized free ester, which, it is clear, could proceed in a very similar series of stages as expressed in the equations:



$$C_6H_5C\begin{smallmatrix}\diagup NH\\ \diagdown OCH_3\end{smallmatrix} + H^+ + OH^- \longrightarrow C_6H_5C\begin{smallmatrix}\diagup \ddot{N}H_2\\ -O\,H\\ \diagdown OCH_3\end{smallmatrix} \longrightarrow C_6H_5CO_2CH_3 + NH_3. \qquad (6')$$

For me, one of the most interesting and important features of our work is found in the unmistakable way in which the fact is brought out more and more clearly that the accelerating or catalytic effect of the acid is most intimately associated with the transformation, in acid solution, of the positive ion of a weaker base into that of a stronger one—the results no doubt of the principle of the loss of a maximum amount of free energy.[3] This is shown most strikingly in the following illustration: whereas the above imido esters are very rapidly decomposed by water in the presence of acid, this is not the case for the closely related compounds, the urea ester salts, which, *structurally considered*, could react quite as easily with water but are as a matter of fact quite stable in acid solution. The transformation



$$NH_2C\begin{smallmatrix}\diagup NH_2^+\\ \diagdown OCH_3\end{smallmatrix} + HOH \longrightarrow NH_2C\begin{smallmatrix}\diagup \overline{NH_3^+}\\ -O|H\\ \diagdown OCH_3\end{smallmatrix} \longrightarrow NH_4^+ + H_2NCOOCH_3 \qquad (7)$$

only takes place to a very slight extent at 100°, and at ordinary temperatures, where imido ester salts are completely decomposed in one to ten hours, the urea ester salts have not been observed to decompose at all.[4] In this case we have the notable fact that such a transformation would involve the change of a salt of a stronger base into that of a much weaker one—an ammonium salt—and this does not take place. To test the legitimacy of our reasoning we recently examined the behavior of benzoyl urea ester salts: the benzoyl urea esters form very much weaker bases than ammonia and our reasoning would lead us to expect that they, in turn, ought to be decomposed quite as smoothly in acid solution as the imido esters. Such is, in fact, the case;[1] urethanes and ammonium salts readily result according to the equation

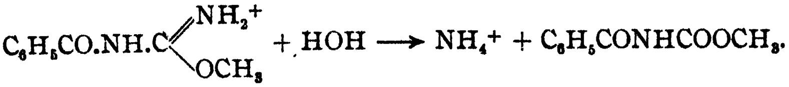
---

[1] See a more complete discussion by Stieglitz, *Am. Chem. J.*, 39, 402.

[2] Stieglitz, *Loc. cit.*

[3] *Ibid.*

[4] The degree of stability is being examined *quantitatively*.



$$C_6H_5CO.NH.C\begin{matrix}\diagup NH_2^+\\ \diagdown OCH_3\end{matrix} + HOH \longrightarrow NH_4^+ + C_6H_5CONHCOOCH_3. \quad (8)$$

We find then that perfect analogy in structure is of far less importance in determining the result of the action of water than a definite physico-chemical relation subject to quantitative measurement.

This is again brought out beautifully by the behavior of the urea esters towards ammonia. The imido esters give with ammonia amidines and again the action is accelerated by the addition of an acid or an ammonium salt and, as we shall see presently, this is due to the fact that again it is the positive ester ion that reacts with ammonia, an amidine resulting according to the equation

$$C_6H_5C(: NH_2^+)OCH_3 + NH_3 \longrightarrow C_6H_5C(: NH_2^+)NH_2 + HOCH_3 \quad (9).$$

Now, urea esters which, as explained above, would not react with *water* in acid solution because the salt of a stronger base would be converted into the salt of a weaker one if they did react, would give with *ammonia* guanidines which are still stronger bases than they are themselves. They should, therefore, according to this theory, react with ammonia in the presence of an acid; as a matter of fact they do, producing guanidines very readily, and we were able to prove again that the velocity of the formation is proportional to the concentration of the positive ester ion;[1] in fact, until our theory led us to recognize the importance of having a salt-forming acid present, all our efforts to prepare guanidines from urea esters—by using ammonia alone—had proved futile; so that this theory seems to agree equally well with the reactions of a given compound which *do occur* as with those which do not take place.

We have found too that in series of structurally closely related esters where what might be called the structural and stereochemical resistances to the action are perhaps approximately the same, the transformation of the positive ion of a weaker base in the presence of acids into that of a given stronger base, say into the ammonium ion, *proceeds with the greater velocity at a given temperature the weaker the original base is.*[3] This brings, as far as I am aware, the first complete experimental proof of a theory which others, notably van't Hoff and Euler suspected to be true,[4] although there appeared so many marked contradictions to the assumption that the theory appeared at best a very uncertain one. For instance, Hemptinne[5] and Lowenherz,[6] working on this problem at van't Hoff's suggestion, obtained the following results for the saponification of esters by acids:

TABLE III.[1]

Ester.	Velocity constant.	Ioniz. const. of the acid.
$HCOOC_2H_5$	0.11	$21 \times 10^{-}$
$CH_3COOC_2H_5$	0.0057	1.8×10^{-5}
$ClCH_2COOC_2H_5$	0 0033	$155 \times 10^{-}$
$Cl_2CHCOOC_2H_5$	0.0053	$5100 \times 10^{-}$
$CH_3CH_2COOC_2H_5$	0 0061	$1.3 \times 10^{-}$

Assuming, as Euler did, that the strongest acids produce the weakest bases in their esters, one might expect the positive ions of the chloroacetic acid esters to be saponified most rapidly to give the positive ion of a *given* stronger base, the oxonium base of ethyl alcohol. As a matter of fact the velocity constants in the above table do not tell us anything at all as to whether that is so or not and that is why the theory, heretofore, has appeared as an unproved one; obviously it does not follow from the data in Table III, where the *weakest* bases, dichloroacetic ester and chloroacetic ester, have the *smallest*, not the largest, velocity constants of decomposition. But the fact that, for instance, the velocity coefficient for the saponification of dichloroacetic ester is even smaller than that for ethyl acetate *does not mean anything at all* in regard to the real *relative rates of transformation of their positive ions*: there is a second factor involved, namely, the concentrations of the positive ions of the esters are dependent on the strength of the esters as oxonium bases, as expressed in our fundamental equations for the catalysis of an ester by an acid.[2] In our fundamental equation

$$dx/dt = K_{v(ion)} \times C_{pos.\ est.\ ion} \times [C_H \times C_{OH}] \qquad (10)^3$$

we may substitute for $C_{pos.\ est.\ ion}$ the relation expressed in:

$$C_{pos.\ est.\ ion} = k_{aff.}/k' \times C_{ester} \times C_H \qquad (11)^4$$

and have

$$dx/dt = K_{v(ion)} \times k_{aff.}/k' \times C_{ester} \times C_H \times [C_H \times C_{OH}] \qquad (12)$$

$$= K_v \times C_{ester} \times C_H \times C_H \times C_{OH} \qquad (13)$$

which is the ordinary equation representing the velocity of decomposition of esters by acids. What we determine with esters, for instance in Hemptinne's and Lowenherz's work as expressed in Table III is K_v and not the *more fundamental constant* $K_{v(ion)}$. Now

$$K_v = K_{v(ion)} \times k_{aff.}/k' \qquad (14)$$

and it is obvious that if the basic strength of the ester as expressed in $k_{aff.}$ grows very much smaller, as it undoubtedly does when we go from ethyl acetate to ethyl chloroacetate, $K_{v(ion)}$ *could easily grow very much larger* and *yet* K_v *need not change appreciably or it might even grow smaller*, without the result being in any disagreement whatever with the theory expressed. This means, of course, that determinations simply of the velocity constants K_v of decomposition of such esters do not prove anything as to the principle at issue. A somewhat stronger base might well give a higher rate of change than a weaker one by virtue of the fact that a larger proportion of the base is present in its active form, the ion, and the real rate of decomposition of the ion may be much smaller than that of an ester giving a smaller velocity constant K_v. The imido esters have the advantage that their affinity constants are easily ascertained and we do not deal with any such unknown quantity at all, and thus we were able to bring what I believe is the first experimental proof of the soundness of the theory. An apt illustration of the correctness of our argument concerning the lack of data for a correct analysis of results like those given in Table III is found in the following facts: the formation of amidines from imido esters, as was stated, is greatly accelerated by the addition of acids or of an ammonium salt and we were able to show that the amidine formation may be considered essentially a function of the concentration of the positive ester ion, proceeding according to

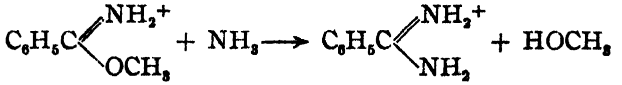
---

[1] The table is taken from Euler, *Loc. cit.*, p. 412.

[2] Stieglitz, *International Congress of Arts and Science*, St. Louis, 1904, **4**, 276 of the report, and *Am. Chem. J.*, **39**, 47 (1908).

[3] $C_{pos.\ est.\ ion}$ is a function of x.

[4] k' is the stability constant of the oxonium hydroxide. $k_{aff.}/k'$ may be considered the stability constant of the complex ester ion. Cf. Bredig, *Z. Elektrochem.*, **9**, 118 (foot-note).



$$C_6H_5C{\Large\langle}^{NH_2^+}_{OCH_3} + NH_3 \longrightarrow C_6H_5C{\Large\langle}^{NH_2^+}_{NH_2} + HOCH_3 \qquad (9)$$

and

$$dx/dt = K_v \times C_{pos.\,est.\,ion} \times C_{NH_3} \qquad (15)^1$$

Now, if we develop the expression for the concentration of the positive ion of a very weak base like an imido ester in the presence of a much stronger one like ammonium hydroxide we find that:

$$C_{pos.\,est.\,ion} = \frac{C_{ester} \times C_{NH_4^+}}{C_{NH_3}} \times \frac{k_{aff.\,est.}}{k_{aff.\,amm.}} \qquad (16)$$

and by substitution we get:

$$dx/dt = K_{v(ion)} \times \frac{k_{aff.\,est.}}{k_{aff.\,amm.}} \times \frac{C_{ester} \times C_{NH_4^+}}{C_{NH_3}} \times C_{NH_3} \qquad (17)$$

$$= K_{v(ion)} \times \frac{k_{aff.\,est.}}{k_{aff.\,amm.}} \times C_{ester} \times C_{NH_4^+}. \qquad (18)^2$$

Now, imido *ethyl* benzoate forms benzamidine considerably faster than does the *methyl* ester: in both cases the change is from the salt of the positive ion of a weaker base to that of a much stronger one, the amidine, but the *ethyl* ester is the stronger base and yet it reacts the faster and apparently contradicts our theory. A knowledge of the affinity constants shows, however, that it reacts the faster only because by virtue of its being a stronger base it takes a larger proportion of the catalytic agent, the acid, from the ammonium chloride, and forms a proportionally larger concentration of the active component, the ester ion, than does the methyl ester under the same conditions. Calculating with the aid

---

[1] $C_{pos.\,est.\,ion}$ is a function of x.

[2] In passing, it may be remarked that this last form shows that the action may be considered one of the ion ammonium acting on the ester, but we believe our original assumption to be the right one for reasons found in the behavior of organic compounds which cannot be elaborated here; it may be said, for instance, that we have found NH_3 and not NH_4^+ to react with ordinary esters to form amides and are carrying out other more crucial experiments on this point. *Vide* Acree, *Am. Chem. J.*, 38, 308. itzgerald and Lapworth, *J. Chem. Soc.*, 93, 2163.

of the affinity constants the true *velocities of transformation of the positive ions*, we find the true relation: $K_{v(ion)}$ for the methyl ester is 140/0.434 and for the ethyl ester only 69/0.434.[1] So the true relations resulting from an exact knowledge of all the quantitative constants involved agree perfectly with the fundamental principle given.

This reaction shows other points of great interest: for instance, the fact that the concentration of ammonia cancels out of the mathematical equation leads to the conclusion that the velocity of decomposition is independent of the concentration of ammonia, one of the reacting components.

This peculiar conclusion has been fully verified by experience; the velocity constant is as a matter of experiment almost, although not absolutely, independent of the concentration of ammonia; in the case of the above methyl ester, the constant grows only about 10 per cent. with an increase of 400 per cent. in the concentration of the ammonia. This apparent contradiction with the law of mass action is readily understood if we remember that the concentration of ammonia has two effects which oppose each other; ammonia does accelerate the action in proportion to its mass as required by the law, but it also to the same degree retards the action by depriving the weaker base of the ionizing and therefore catalyzing acid. Within a year Lapworth[2] has made the extremely important discovery that water stands in exactly the same relation to the esters in the catalysis by acids—only then the two bases competing for the acid are two oxonium bases, the ester and water.

And now in conclusion I wish to call attention to one more result with these imido esters which has impressed us very much and which seems to me to throw a very clear light on the whole question of catalysis or acceleration by showing certain limitations to catalytic effects. It was mentioned a moment ago that the velocity of formation of benzamidine from methyl imido benzoate may be expressed as a function of the positive imido ester ion and that it is almost independent of the concentration of the ammonia; but it is not absolutely independent, there is a slight but steady rise in the value of the constants with increasing concentrations of ammonia. All other secondary reactions having been excluded (*e. g.*, for fourfold increase of NH_3, the constants rise gradually from 139/0.434 to 154/0.434) as the cause of this increase by a knowledge of their velocity constants, we suspected that besides the main action of ammonia on the positive ester ion, there is a much slower action of ammonia also on the non-ionized free ester, namely, that we have two simultaneous actions:

$$C_6H_5C(:NH_2^+)OCH_3 + NH_3 \longrightarrow C_6H_5C(:NH_2^+)NH_2 + HOCH_3 \quad (18)$$

and

$$C_6H_5C(:NH)OCH_3 + NH_3 \longrightarrow C_6H_5C(:NH)NH_2 + HOCH_3 \quad (19)$$

We had the more reason to suspect this as we had already found that water, besides decomposing the positive ion of an imido ester at a very high speed, also undoubtedly decomposes the non-ionized ester at a very slow rate.[3] It was found that the experimental results agree very well with this conception of two simultaneous actions in the formation of

[1] Miss Katharine Blunt's dissertation (1907).

[2] *Loc. cit.*

[3] In this case the products are different. *Vide* Stieglitz, Derby and Schlesinger, *Loc. cit.*

benzamidine and that the velocity constant for the action of ammonia on the positive ester methyl ion at 25° is 325, while that on the ester molecule is only 0.0069.[1] That is, the positive ion is almost 50,000 times as reactive as the non-ionized molecule. It may appear somewhat surprising that such a small constant could still be detected side by side with such an enormous one, the whole action being completed in one to two hours. But we must remember that for the ion action with the enormously high rate of change we have at any moment only minute quantities of the reacting component, *e. g.*, 0.000,005 gram ion at the beginning of a velocity measurement, which is used up at an enormous speed but always formed again instantly by the purely ionic action of imido ester on the ammonium chloride. On the other hand the transformation of the non-ionized molecule has the advantage of relatively high concentrations of each of the reacting components, say 0.05 both for the ammonia and for the free ester at the beginning of an action. With a concentration many thousand times in its favor it is then not surprising to find this very slow action becoming perceptible in careful quantitative work. Now, if we should use a much weaker base still, we might easily find the action with the non-ionized ester taking a *more and more prominent part* in the total change, even if the actual rate of change of the positive ester ion should still be very much the greater. We have recently found such to be the case for the action of ammonia and ammonium chloride on benzoyl urea ester:[2] the velocity constants are so nicely balanced against the affinity constants that the observed changes did not agree even approximately with either conception used alone, *viz.*, that the guanidine formation was due to the action of ammonia on the positive ester ion alone, or on the non-ionized ester alone. But they did agree well with the view that both actions occur simultaneously, the velocity coefficient for the action on the ion being 34.5 and the coefficient for the action on the non-ionized ester being 0.0015, a ratio of 23000 to 1 again. We were exceedingly pleased to find this case because it forms the connecting link with what we have found to be true for the formation of ordinary acid amides from acid esters in the presence of ammonia and ammonium salts:

$$CH_3COOCH_3 + NH_3 \longrightarrow CH_3CONH_2 + HOCH_3 \qquad (20).$$

This action seems to be essentially a function of the ester and ammonia and it is an extremely slow reaction.[3] We can easily understand this case now; the esters as extremely weak oxonium bases must be able to take only the faintest traces of acid from the ammonium chloride in the presence of ammonia and therefore the slow molecular transformation comes to the front as enormously favored by the concentrations of the reacting components. In the case of the actions of acids on esters and water, the esters compete only with an oxonium base of the same order of strength as they are themselves and rather weaker,[4] the oxonium base of water and here the reaction with the ion is again predominant.

These studies then show us a whole range of organic compounds, obviously of the *same type* and *family* but giving reactions which proceed quite differently with the imido esters the action of ammonia on the *positive ion* is the essential action and the use of a catalytic agent,[1] an acid is advisable, in fact, necessary; with ordinary esters the action on the ion becomes negligible because the ion simply cannot be produced in sufficient quantity under these conditions and the action *of ammonia on the non-ionized ester becomes the essential action.* The addition of acid as a catalytic agent is *practically ineffective* and therefore inadvisable. But these apparently disconnected results are now easily understood as being perfectly consistent and logical—the one case representing an almost but not quite pure type of one of the *two natural simultaneous reactions*—the enormously rapid action of the ammonia on the *imido ester ion*—and the other case representing the almost pure type of the other simultaneous action, the extremely slow action of ammonia on the non-ionized ester molecule. And the connecting link is found when the adjustment of the affinity and the velocity constants involved bring *both actions out prominently at the same time.* Of course one must then expect every possible class of reactions lying between these extremes. The results show plainly then, I believe, why a catalytic agent will work smoothly in a number of cases, and why it will fail utterly in accelerating actions apparently of exactly the same organic type, *differing only in the numerical value of the physico-chemical constants included in the final expression governing the action of a catalytic agent.* We have been using the imido esters *simply as a kind of magnifying glass* to *measure* all these constants and thus to enable us to recognize some of the general underlying principles which govern catalysis by such chemical agents, as acids, bases and salts.

---

[1] Mr. Norton is collecting more data on these relations.

ON THE BIOCHEMISTRY OF NUCLEIC ACIDS.[2]

BY P. A. LEVENE.

Received December 2, 1909

Life is the most complex phenomenon in nature and its manifestations are innumerable. They all mysteriously arise in the living organism and are all harmoniously centered in it. This, even in its simplest form is the most perfect laboratory, the seat of an infinite number of chemical reactions, none of them interfering with the equilibrium of the others. The substances produced by the most primitive of the living organisms are as large in number as they are varied in their properties. The discoveries of new substances manufactured by the plant or animal cell are not yet exhausted and for ages the chemist dreamed of no better reward for his labors than the finding in tissue juices of a new body with properties hitherto unknown. The living organism was the only retort, vital force the only reaction in his possession that could furnish him with carbon-containing substances. In that sense every chemist in those days was a biological chemist.

In the year 1828 a startling discovery was announced. Wöhler wrote to Berzelius: "I must tell you that I can make urea without the aid of the kidney, or generally without the living organism whether of man or dog," and four years later the divorce of biological and organic chemistry was apparently accomplished when Wöhler and Liebig laid the foundation of the organic chemistry of to-day by their work on the radicle of benzoic acid. However, the divorce was only apparent, for the reason that only the knowledge of molecular constitution made it possible to establish the relationship between the organism and the chemical bodies manufactured by it, only the knowledge of the dynamics of the chemical reactions could coördinate the observations of the functions of the living organism, and of the accompanying changes in the composition of the living cells.

---

[1] *Loc. cit.*

[2] Presented at the Second Decennial Celebration of Clark University, Worcester, Mass., September 15, 1909.

The attitude of the biological chemist was altered. He saw his new goal in disclosing the nature of chemical reactions occurring within the living cell and finding their bearing on the manifestations of life.

If time permitted I would present to you the progress of all the work done in that direction in recent years. Within the narrow limits of this report, however, this is impossible to accomplish with any degree of justice to the subject and I shall, therefore, limit the discussion to only one phase, namely, to the work bearing on the chemical interpretation of one of the most cardinal properties of living matter.

Living matter is distinguished from inanimate by the fact that it undergoes cleavage and oxidation at a very perceptible velocity, and that the restoration of the loss sustained in that manner takes place at approximately the same rate. Thus the function of automatic regeneration lends to living matter its principal peculiarity.

Great credit is due to the biologist for the discovery that in an organized cell this function is seated in a formation possessing definite chemical properties, named chromatin or nuclein. At a time when the process of regeneration is very active, namely, during the development of the fertilized egg, the rate of the new formation of nuclein rises to a very perceptible degree, and the observer is led to see a genetic relationship between these two processes.

Our distinguished biologist, Jacques Loeb,[1] was the first to express the function of reproduction in terms of chemical reactions. In his address to the International Congress of Zoologists held in Boston in September, 1907, he stated: "If the question be raised as to what is the most obvious chemical reaction which the spermatozoan causes in the egg, the answer must be an enormous synthesis of chromatin or nuclear material from constituents of the cytoplasm." Thus, it becomes evident that the knowledge of the mechanism of regeneration is dependent on the knowledge of the chemistry of nucleins.

I shall for a moment forestall the systematic discussion of the chemical nature of nucleins by mentioning that at the time of Loeb's address we were in possession of considerable information on the composition of these substances. It was known that phosphoric acid entered into the formation of the molecule. Therefore, it became evident to Loeb that a supply of phosphoric acid was required in order to make a synthesis of nucleins possible. In a developing egg the phosphoric acid was furnished by the cell itself, for the formation of nucleins proceeded also when the eggs were placed in a medium free of phosphoric acid. The other components of the cell that are known to contain phosphoric acid in their molecule are the lipoids. In these substances phosphoric acid

[1] University of California Publications in Physiology, 3, 61–81 (1907).

is present in an ester-form combination, and Professor Loeb proceeded to argue that the first phase in cell reproduction *à priori* ought to consist in the saponification of its lipoids. This assumption was brilliantly verified in his experiments on artificial parthogenesis. He brought to light the fact that dissolution of the lipoids is actually the process which precedes the nuclein synthesis and the segmentation of the nucleus. He further demonstrated that agencies facilitating this saponification were able under favorable conditions to start the development of an unfertilized egg without the aid of spermatozoa. Thus only an elementary knowledge of the chemical nature of two cell components furnished Professor Loeb with the power at will to start or to impede cell development by chemical means, and in a way to furnish evidence that the function of regeneration was a chemical process. But the process of nuclein synthesis in the active cells is not yet disclosed in its harmonious entirety, and no one can entertain any hope of arriving at this knowledge without the discovery of the chemical constitution of nucleins.

The considerations that attracted the attention of so many chemists to the work on the chemical nature of these substances, therefore, are becoming very obvious, and I shall attempt to present the results and the achievements of the numerous endeavors towards the solution of this very difficult problem.

The first important contribution to the chemistry of nucleins was made by Altman, a biologist.[1] Altman was in possession of the information that nucleins were endowed with the properties of fairly strong acids, and further that they were quite resistant to the action of pepsin hydrochloric acid. The latter property enabled him to prepare considerable quantities of nuclein by removing the protein part of the tissues by means of peptic digestion, and the fats by the usual extractives. The remaining nuclein he found to consist of a protein combined with a conjugated phosphoric acid. The acid he named "nucleic acid." By means of alkaline hydrolysis, Altman succeeded in removing all the protein from his nuclein so that the final product analyzed by him refused to disclose any trace of protein even by the aid of the most sensitive color test.

The further development of the chemistry of nucleic acid was accomplished through the investigations of Miescher, of Schmiedeberg and his pupils, of Kossel and his school, by Haiser, G. H. Hammarsten and his pupil Ivar Bang, and in this country by the work of T. B. Osborne, of Walter Jones, and of my co-workers and myself. I must, however, add that the purest nucleic acid was obtained by the man who was first in so many lines of chemical activity, Liebig, although on this occasion he failed to discover the real significance of his finding.

I shall make no attempt to present all the work on nucleic acid in its chronological order, but I shall refer to individual investigations in connection with the discussion of the development of the various phases in our knowledge of chemical structure of those complex acids.

The three principal phases in the endeavors to reveal the nature of nucleic acid consist: first, of work aiming to obtain the substance in a convenient manner, and in a possibly unaltered condition with a view to ascertain the elementary composition of the substance; second, in the work directed towards finding all the components of the various nucleic acids; and third, in determining the actual structure of the molecule; or in other words the manner of arrangement of the individual components within the molecule.

Ultimate Analysis of Nucleic Acids.

I shall touch only briefly on the first phase of the work, for the reason that it is of interest principally to the men personally engaged in it. The achievements obtained through that work are not very significant. Only in connection with the study of inosinic acid, a nucleic acid of beef muscle, the elementary analysis was of unmistakable service in ascertaining the composition of the substance. It was the first and thus far the only instance that a salt of a nucleic acid was obtained in a crystalline form. The fact that no other nucleic acid has been prepared in an absolutely pure condition renders the conclusions drawn from their analysis only of secondary value. The workers who contributed to the improvement in the methods of preparation of the substance are: Altman, Miescher, Schmiedeberg, Kossel, Neumann, Hammarsten, Bang, Haiser and myself.[1]

The methods of preparation and of purification of the substance employed by individual workers differed greatly either in principle or detail. Under such circumstances marked divergence was noted in the analytical figures obtained by different investigators for nucleic acids even of the same origin. The following table illustrates some of these discrepancies.

TABLE SHOWING THE ELEMENTARY COMPOSITION OF VARIOUS NUCLEIC ACIDS.

	C.	H	N.	P.	O.	Base.
I. Thymonucleic acids of animal origin:						
1 Fisch sperm:						
a Salmon (Miescher and Schmiedeberg)	37.8	4.5	15.8	9.7	33.2	....

2 Wheat embryo (Osborne and Harris)	33.1	4.2	14.9	8.1	...	....

In adopting an empirical formula for the nucleic acids the individual investigators were guided not only by the analytical figures, but also by considerations of a speculative nature based to some extent on information obtained on partial or complete hydrolysis of the acids. The basis for the speculations of the different workers varied considerably. This led to a great divergence in the views on the empirical formula of nucleic acid. The following table contains some illustrations of it:

	C.	H.	N.	O.	P.
Schmiedeberg[1] (spermnucleic acid)	40	56	14	26	4
Steudel[2] (thymus nucleic acid)	43	57	15	26	4

Levene[7] (yeast nucleic acid)	38	50	15	29	4

The Components of Nucleic Acids.

It has been stated that the first knowledge of the chemical nature of nucleic acids was limited to the information that it was a conjugated phosphoric acid. The first work of Altmann was followed by that of Kossel. The efforts of this investigator were directed towards the analysis of the products of hydrolytic cleavage of nucleic acids. His first achievement was the discovery of purine bases in the molecule of nucleic acids. These bases can be obtained on cleavage of nucleic acids with very dilute solutions of mineral acids. Kossel further devised methods for the separation of the individual bases. He arrived at the conclusion that four purine bases, namely, adenine, guanine, hypoxanthine and xanthine, enter into the molecule of nucleic acids. This view, however, was later revised as it was established that only two purine bases, adenine and guanine, actually enter into the composition of nucleic acids. Hypoxanthine and xanthine are now regarded as secondary products.[1] However, it was evident from the figures obtained on elementary analysis of nucleic acids, that their molecule contained substances other than purine bases. On the basis of the observation that on hydrolysis with dilute mineral acids only the purine bases are liberated and the other components remain intact, there was advanced a theory that in nucleic acids the phosphoric acid is combined with a complex radicle forming a conjugated phosphoric acid, and that this in its turn combined with the purine bases. The manner of this combination was the subject of considerable discussion and disagreement.

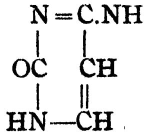
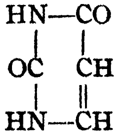
[7] *Biochem. Z.*, 17, 120 (1909).

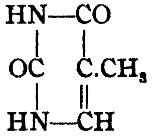
The efforts to elucidate the composition of the complex radicle resulted in the discovery of the following purine derivatives.[2]



Cytosine.



Uracil.



Thymine.

However, in order to obtain these substances it was necessary to resort to the hydrolysis by means of mineral acids of considerable concentration. This procedure caused many investigators to express doubt as to the presence of the pyrimidine bases in the nucleic acid molecule. The doubt was particularly great regarding the orgin of cytosine and uracil. R. Burian[3] with great persistence defended the view that these two bases took their origin in the partial cleavage of the purine ring. However, the majority of workers were inclined to consider cytosine also as a primary constituent of the molecule of nucleic acids, while uracil was considered a primary product in the acids of plant origin only.

Besides the purine and pyrimidine bases the molecule of nucleic acid was found to contain carbohydrates. The complex nucleic acids of animal origin contain a hexose, the exact nature of which is not yet established. The nucleic acid of plant origin and the simpler nucleic acid of the animal tissues contain a pentose. On the basis of the work of Neuberg[4] the pentose was considered *l*-xylose. However, very recently Jacobs and I have succeeded in isolating the substance in crystalline form. This made it possible to establish the true nature of the substance as *d*-ribose.[5]

As the methods of analysis had improved, and as approximately quantitative estimation of the components was made possible, it was found that in nearly all the acids the bases were present in approximately equimolecular proportions, that the number of molecules of phosphoric acid corresponded to that of the bases, and the number of molecules of carbohydrate was equal to that of phosphoric acid.[1]

---

[5] Levene and Jacobs, *Ibid.*, 42, 2102, 3247 (1909).

On the basis of these calculations, and on the basis of the numbers of the character of the bases entering into the molecule of the individual nucleic acids the following classification could be established:

1. Nucleic acids: Containing one purine base (no pyrimidine), a pentose and phosphoric acid. (Inosinic acid, guanylic acid.)
2. Nucleic acids: Containing two purine bases (guanine and adenine), two pyrimidine bases (cytosine and uracil) and phosphoric acid. (Phytonucleic acids.)
3. Nucleic acids: Containing two purine bases (guanine and adenine), two pyrimidine bases (thymine and cytosine), and a hexose and phosphoric acid. (Nucleic acid of animal tissue—thymonucleic acids.)

The Constitution of Nucleic Acids.

The early speculations regarding the constitution of nucleic acids were based on the results of partial hydrolysis by means of dilute acids or weak alkalies. Reference has been made already to the views expressed by Kossel.[2] By mere heating with water under increased pressure, this author thought he obtained a substance, which was free of purine bases, but contained all the other components of the original nucleic acid. The substance was named thymic acid. Nucleic acid was regarded therefore as a complex consisting of thymic acid and of purine bases. The author did not furnish any detailed information regarding the nature of thymic acid. Somewhat more definitely formulated was the view of Schmiedeberg. According to this author there existed a complex—nucleotin, this complex combined with phosphoric acid to form nucleotin phosphoric acid, and this acid in its turn combined with purine bases thus forming nucleic acid. Schmiedeberg ascribed to the nucleotin the formula $C_{30}H_{42}N_4O_{13}$. Alsberg,[3] working in Schmiedeberg's laboratory, actually succeeded in obtaining a substance which had the composition of the hypothetic nucleotin. However, these writers also failed to disclose the constitution of the complex radicle. In fact, they failed to furnish evidence that their substance was not a mixture composed of several cleavage products of nucleic acids.

Results of actual significance for the interpretation of the structure of the nucleic acid were obtained only recently. The point of departure for the work was the study of inosinic acid by Levene and Jacobs. As has already been pointed out this acid is comparatively simple in its composition. It is composed of phosphoric acid, a pentose and hypoxanthine. Through prolonged action of dilute acid at the temperature of 50° it was possible to break up the molecule into hypoxanthine and a pentose-phosphoric acid.[1] This substance was obtained by Jacobs and myself in the form of its crystalline barium salt. This acid had all the properties of a conjugated phosphoric acid, and on cleavage yielded the phosphoric acid. The acid reduced Fehling's solution on heating without previous hydrolysis. It was concluded from this that in the molecule the phosphoric acid and the carbohydrate are bound in ester-form, and that the aldehyde group of the pentose phosphoric acid was free and that therefore in the inosinic acid the base and pentose were coupled in a glycoside union. This assumption was strengthened by the fact that inosinic acid was found to be very resistant towards the action of alkalies even at fairly high temperatures, and even on prolonged boiling the acid underwent only partial hydrolysis with formation of phosphoric acid and of the complex: pentose-base. Furthermore, it wasfound that by hydrolysis at nearly neutral point the conditions for the reaction were more favorable and it was possible in this manner to isolate and to identify the pentoside-inosine ($C_{10}H_{12}N_4O_5$). On the basis of this we concluded that the order of combination of the components in the molecule of the inosinic acid was established. I could add here that only on hydrolysis of the pentoside was it possible to obtain the crystalline sugar which was identified as *d*-ribose. The structure of the complex pentose-hypoxanthine may be represented in the following manner:

---

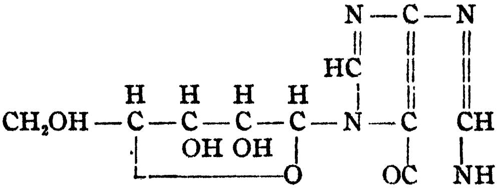
[3] Schmiedeberg, *Arch. exp. Path. Pharm.*, **43**, 57 (1900). Alsberg, *Ibid.*, **51**, 239 (1904).



The same substance had been found by Haiser and Wenzel in beet extract.[2]

Regarding the place of the purine base which entered into union with the sugar, there still remains only the evidence of Burian that place 7 is attached to the sugar and no information exists regarding the place of the hydroxyl in the pentose that is coupled with the phosphoric acid.

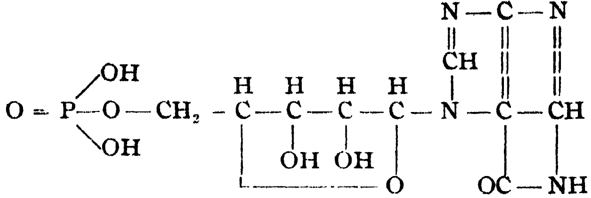
The following step in the progress of the work was the application of the experience obtained on inosinic acid to the other nucleic acids. Jacobs and I next directed our attention to the remaining acid of comparatively simple composition, namely guanylic acid. Employing the same methods of hydrolysis as applied to inosinic acid, we obtained guanosine ($C_{10}H_{13}N_5O_5$), a substance analogous to inosine; it possessed nearly the same crystalline form, differed in its physical constants, and on hydrolysis gave guanine and the same pentose as the inosine, namely *d*-ribose. This pentoside had the same properties as inosine in its behavior towards alkalies and acids.[3] For the sake of convenience we named the substances of this order "nucleosides" and the combination of the nucleoside and phosphoric acid we named "nucleotides." Thus according to that nomenclature inosine and guanylic acid were to be regarded as mononucleotides of the following structure:

---

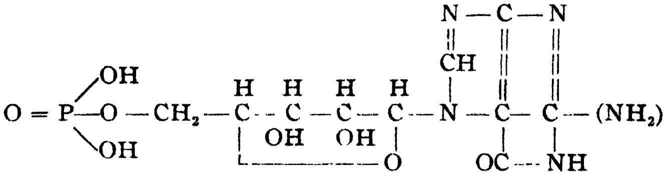
[1] *Ber.*, 44, 2703 (1908).

[2] Haiser and Wenzel, *Monatsh. Chem.*, 29, 157 (1908)

[3] *Ber.*, 42, 2474 (1909).

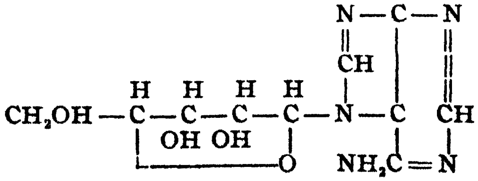


(Inosinic acid)



(Guanylic acid.)

The further application of the same methods to a more complex nucleic acid, to that of the yeast, led to the conviction that this also was composed in the same manner. Thus the same nucleoside-guanosine, as obtained from guanylic acid, was also found on hydrolysis of the yeast nucleic acid. When the proper conditions are observed the nucleoside can be chilled out and a nearly quantitative separation accomplished. In the filtrate from this nucleoside other substances of the same nature were expected. On the basis of considerations expressed by me in an earlier article on the composition of the yeast nucleic acid the molecule of the acid is composed of four nucleotides and therefore four nucleosides should be found on cleavage of the substance. The work in that direction is of comparatively recent date, and a second nucleoside has already been obtained from the mother liquor of guanosine.[1] The second nucleoside has practically the same crystalline appearance as inosine or guanosine, and differs from these two only by its physical constants and by the fact that on hydrolysis it yields in place of guanine the base adenine, and is, therefore, named adenosine. Also on hydrolysis of this nucleoside the crystalline *d*-ribose is obtained. The substance therefore had the following structure:



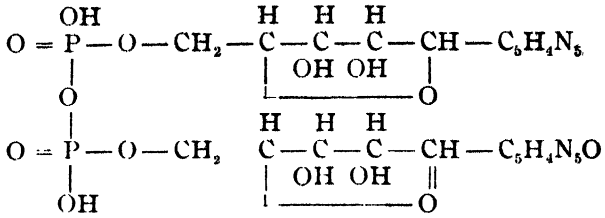
It possesses the melting point of 229° and the rotation: $[\alpha]_D = -67.30°$.

On the ground of this the structure of the yeast nucleic acid may be presented in the following manner:[2]

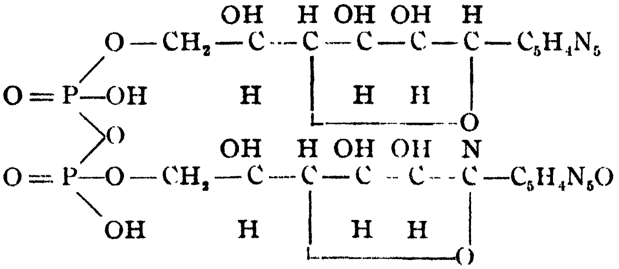
---

[1] Levene and Jacobs, *Ber.*, 42, 2703 (1909).

[2] Bloch, *Zeitsch.*, 120, 17 (1909).



All this work is of comparatively recent date so that as yet it could not have been extended to the analysis of thymonucleic acid. But evidence had been furnished that this substance also has a structure analogous to that of the yeast nucleic acid[1] In fact considerations based on the work on thymus nucleic acid were the first that led to formulating the structure of the complex nucleic acid as a polynucleotide, of which the individual mononucleotides were composed of phosphoric acid, sugar and base. Levene and Mandel have on hydrolysis of the spleen nucleic acid with dilute sulphuric acid obtained a substance which had the elementary composition ($C_{11}H_{17}N_2PO_{10}$) of a complex consisting of phosphoric acid, hexose and thymine. On cleavage with 25 per cent. sulphuric acid this body gave rise to phosphoric acid, levulinic acid and thymine. This assumption is in harmony with subsequent discoveries on the simple nucleic acid and on the yeast nulceic acid, and one feels justified in formulating the structure of thymonucleic acid in the following manner:



Thus the details in the structure of the molecule of nucleic acids are not yet known. But some general information is already obtained and the route is singled out, by which the solution of the problem will be reached. An indication is given for a point of departure for the work on the synthesis of these substances. Work in that direction is now in progress in our laboratory.

THE ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH,
NEW YORK CITY.

NEW BOOKS.

General Inorganic Chemistry. By CHARLES BASKERVILLE, Ph.D., Professor of Chemistry in the College of the City of New York. Boston, Mass.: D. C. Heath & Co. 1909. pp. vii + 357.

This book is of considerable interest as Professor Baskerville has departed from what has become the more or less standard method of presenting the facts of inorganic chemistry. The compounds described are not classified according to the metals which they contain, but according to the negative element which is present, or the acid from which they are derived. The elements are first considered, and then the oxides, sulphides, nitrates, sulphates, etc. The classification within these groups is according to the Periodic Law.

---

[1] *Ber.*, 41, 1905 (1908).

In the first chapter the student is introduced to chemical phenomena through experiments, which are described in detail These are selected to illustrate the fundamental concepts and laws of chemistry, which are appropriately emphasized. A brief chapter on the chemical elements follows, and then certain typical elements and compounds, together with their more important reactions are described at some length. Chapters are devoted to hydrogen, oxygen, water, the halogens, the halogen acids, alkali metals, nitrogen and ammonia, the air, carbon, carbon hydrides, carbon oxides, and valence. A study of these chapters prepares the student for the more logical treatment of the elements and compounds which follows. The Periodic Law is next discussed in some detail, and then the elements are described according to the relationships indicated by the law. The compounds are next considered in the order, halides, oxides, hydroxides, sulphides, hydrosulphides, carbonates, silicates, nitrogen oxides and hydroxides, sulphates, oxides and sulphides of manganese, oxides and sulphides of Group VII, binary compounds of Group IV and V, and compounds of carbon and nitrogen. There are unusually full chapters on radium and alloys.

The novel order of treatment which has been adopted has many apparent advantages and some disadvantages. Among the advantages is the readiness with which relationships between compounds of analogous composition can be pointed out, and the effect of the nature of the more positive element in a compound on reactivity and general chemical properties can be emphasized. Among the disadvantages is one of pedagogical importance. In the usual method of presenting compounds according to the metal which they contain, the discussions of oxides, sulphides, nitrates, etc., which come at intervals, make it possible to review frequently, in a brief manner, the facts already acquired. Repetition is an important factor in memory. According to the author's arrangement a great many related facts are learned at one time, and then more or less dismissed. The proof of the method is in its application, and according to the author, the method has led to successful results with a large number of students, over a period of several years.

The arrangement of facts in the way adopted has led to the description of a great many compounds which are not ordinarily considered in elementary textbooks. The book contains a mass of facts, stated very briefly. Although the text contains but 336 pages, the index covers 20 pages, each containing two columns.

The theoretical considerations are contained in two chapters placed in about the middle of the book: one on molecular weights (six pages), and one on the theory of electrolytic dissociation (five pages). In addition, there are a few brief references to such subjects as valence, reversible reactions, etc., scattered throughout the text. The theory appears to be given for the sake of the theory itself, and not on account of its value in interpreting chemical phenomena; little application is made of it in the treatment of compounds or reactions which are discussed in subsequent chapters.

The book is strikingly original and will, no doubt, appeal to many teachers. A student who has mastered its contents will know more facts of inorganic chemistry than can be learned by a study of many books twice its size. JAMES F. NORRIS.

Experimentelle Untersuchungen über Atomgewichte. VON THEODORE WILLIAM RICHARDS und seinen Mitarbeitern, 1887–1908. Mit 34 Abbildungen im Text Deutsche Ausgabe besorgt von J Koppel. Hamburg und Leipzig. Verlag von Leopold Voss. 1909 vi + 890 pp. Price, 35 marks.

A felicitous outcome of the delivery of a course of lectures in the University of Berlin by Professor Richards has been the publication of this substantial and important volume. About a fifth of its pages now appear for the first time in a German translation; the matter reprinted from a previous translation has been revised only to make it more faithful to the English original.

The first article is entitled "Die in Harvard ausgeführten Atomgewichtsbestimmungen"; the included bibliography gives the titles of 63 papers. Four of these contain the work of Cooke on antimony and of Huntington on cadmium, and antedate Richards' activity. Nine of the more recent do not mention his name as author. Of the remainder, 43 papers, filling 850 pages of this reprint, bear his name, and 19 of them, with their 330 pages, bear his name alone. These 43 together with three others needed for completeness of presentation, contain determinations of the atomic weights of no less than 19 elements: a magnificent body of work of the highest attainable accuracy.

EDWARD W. MORLEY.

Treatise on Qualitative Analysis. By J. F. SELLERS. Second revised edition, 173 pp. Ginn & Company. 1909. Price, $1.00.

Treatise is the proper title for this little work. It deals with qualitative analysis from all sides. Almost half of the book is taken up with theoretical considerations, explanations of analytical operations and additional notes. The application of physical chemistry to analytical chemistry is developed strongly and the presentation of this part is made very clear and attractive.

The part devoted to the detection and separation of the metals and acid radicles covers about the same ground that is included in most of the smaller works on this subject. The value of making comparisons between reactions brought about by the same reagent acting upon different solutions is left for the student to see for himself, it is not brought out here.

For training "future chemists" this book is inadequate, but foi students taking the course in a general way it is remarkably well adapted as it points out plainly that there is something to qualitative analysis beside color and solubility of precipitates, and the separation of the "six groups," a point entirely missed in many courses and most books. O. L. SHINN.

A Manual of Qualitative Analysis. By J. F. MCGREGORY. 133 pp Ginn & Company 1909 Price, $1.00.

This differs from most books on this subject in the arrangement. Groups and group reactions are not spoken of until all of the metals and the acid radicals have been studied separately. The groups are only discussed in the line of separations and the comparisons between the different metals are not made apparent. This method of treatment appears to multiply isolated facts and add confusion to the mind of the student. The term ion and the theory of dissociation are not used, and the old term radical is retained. The use of tables or schemes for group separations is condemned but one method of separating each group is described in the text.

The author states in the introduction that the book is not designed for those who intend to become chemists, but for those who can spend but a short time on this subject. For such students it would be a satisfactory book. O. L. SHINN.

An Introduction to Chemical Analysis for Students of Medicine, Pharmacy and Dentistry. By ELBERT W. ROCKWOOD, M.D., Ph.D. Third edition, illustrated, 247 pages. Philadelphia: P. Blakiston's Son & Co. Price, cloth, $1.50 net.

The first edition of this excellent laboratory guide was reviewed in THIS JOURNAL, **24,** 287. This third edition contains some new matter, and is especially characterized by the attention paid to the ionic interpretation of reactions. The preparation of a satisfactory book for a special class of students who have but a limited time to devote to chemistry is not an easy problem under any conditions; in the case of a work for medical students which must be full enough to prepare for physiological chemistry the difficulty is very great. Medical courses are already badly overcrowded.

The present book does not make any undue requirement on the time of the medical student, or call for more work than he should be expected to cover in his preparation for medicine. It presents a good outline of qualitative analysis and the minimum of the theory and practice of volumetric methods which may be considered necessary to fit the student for practical applications in later years of the course. There are also sections on the analysis of water and on the detection of poisons, and a long section on the identity tests for a considerable number of organic substances. The mechanical work on the book is excellent..

J. H. LONG.

Quantitative Chemical Analysis: Adapted for Use in the Laboratories of Colleges and Schools. By FRANK CLOWES, D.Sc., Lond., and J. BERNARD COLEMAN, A.R.C.Sc., Dublin. 8th Ed., 565 pages. P. Blakiston's Son & Co., Philadelphia. 1909. Price, $3.50 net.

The fact that this book has passed through eight editions (the first edition appeared in 1891) is a good indication of the favor with which it has been received. Indeed, the work is a standard in England, and here in America it has met with no small amount of success. Barring the translation of the Fresenius by Cohn, we know of no work on quantitative analysis in the English language which contains so much useful reliable and varied information. The text of the recent edition has been thoroughly revised, the type has been reset, and many improvements and additions have been made. The subject matter is arranged in eight parts, which are subdivided into eighteen sections: Part I is devoted to preliminary and general operations, Part II to gravimetric analysis, Part III to volumetric analysis, Part IV to complex quantitative estimations, Part V to the analysis of organic substances and the methods for determining molecular weights, Part VI to gas analysis, Part VII contains the results of a number of typical analyses as well as a fine set of reference tables, and Part VIII treats of the preparation of gases, the use of compressed gases, the distillation of water, etc. It also embraces a list of books for reference.

Among the additions of new matter we note in particular a section on the analysis of oils, fats and waxes, a number of electrolytic methods for determining some of the metals, and a description of, and the directions for using, the bomb calorimeter for coal valuation.

The book has a pronounced English flavor. It is written along conservative lines, theoretical matters have been omitted, and only those methods have been described which the authors regard as truly useful and well established. From the standpoint of the reviewer there are, in certain cases, methods of separation and determination which are superior to those cited by the authors. As examples he would mention Neher's admirable method for separating arsenic from antimony, Classen's electrolytic method for separating antimony from tin, and Penfield's device for determining water in rocks and minerals. We notice that in discussing the operation of filtration no mention is made of the Neubauer crucible. Further, the reviewer does not think that sufficient attention has been paid to the determination of silica in the silicates. The names of the discoverers of methods are only occasionally given, and no direct references to the chemical literature accompany the descriptions of processes. It is rather remarkable that in the list of books and journals Mohr's classic work on volumetric analysis and Fresenius' *Zeitschrift* find no mention. These, however, are minor shortcomings when we consider the excellence of the book as a whole. It is essentially a *practical* treatise on analysis, wide in scope, clear in its descriptions, and generally reliable in its methods. The type and paper are good, and the book is well bound. It is also provided with a good index. We welcome the appearance of this 8th edition, and take pleasure in warmly recommending it not only to teachers and students, but to analysts in general.

LEROY W. MCCAY.

Anleitung für das organisch präparative Praktikum. FRANZ W. HENLE. Leipzig: Akademische Verlagsgesellschaft m. b. H. 1909. 8vo. 176 pp., 43 figs.

The attempt has been made, and that quite successfully, to present each preparation not as an individual synthesis but rather as a type of a general class of reactions. This is partially accomplished by the method of presenting the experimental directions but even more by the numerous citations to the original literature discussing the typical reactions of the class of substances under discussion. It is the opinion of the reviewer that the author has made plain to the student the need for the use of the original literature and thereby there will be much less occasion for the almost universal complaint that students engaged in organic preparations do not recognize the importance of reading the original literature.

Coming as it does from Thiele's laboratory at Strassburg, one expects, and finds, it to be thoroughly up to date in the references to the theory of the reactions as well as in the inclusion of examples of the Grignard, Sabatier and other modern syntheses.

It is one of the best of the more advanced manuals and like the others (Fischer, Gatterman, etc.) it will probably give its best service when preceded by a *short* course in which the simpler preparations of the aliphatic series are studied.

RALPH H. MCKEE.

Kolloidchemische Beihefte. By DR. WO. OSTWALD. Volume I, Nos. 1 and 2 Theodore Steinkopff, Dresden. To subscribers of the Kolloid-Zeitschrift 1 M., single volumes 1.20 M.

The object of this publication is to collect together and to present as early as possible the most important general articles on colloids. This is to be a supplement to the Kolloid-Zeitschrift. It should enable those who wish to follow the general advance of the subject to do so without having to discover or recognize for themselves the most important papers for that purpose. Thus, the monographs of Wolfgang Ostwald will differ from those of William Ostwald by being confined to a single subject and by being published as nearly as possible at the time of the completion of the experimental work.

W. R. Whitney.

Metallographie: Ein ausführliches Lehr-und Handbuch der Konstitution und der physikalischen, chemischen und technischen Eigenschaften der Metalle und metallischen Legierungen. Dr. W. Guertler. Erster Band: Die Konstitution. Heft. I., Berlin, Gebrüder Borntraeger. 1909. 80 pp. Price, M. 4.20.

Dr. Guertler has planned a comprehensive treatise on metallography. In this volume, which deals almost exclusively with the theoretical side of the subject, he discusses the constitution of binary alloys. After reviewing the early development of the science, equilibrium diagrams of binary mixtures are discussed from the point of view of the phase rule, solid solutions and compounds are studied, and the cooling curves of the alloys manganese-iron, iron-cobalt, and nickel-cobalt are considered in detail.

It is difficult to discuss in detail so small a part of an extensive treatise, but Dr. Guertler is especially well fitted to undertake a comprehensive work such as he has planned, and so far he has succeeded admirably. The book will be difficult for all except those who have had considerable training in physical chemistry. The discussion of some of the diagrams seems unnecessarily complicated, and it is believed that the practical methods of metallography should have been discussed as early as possible so as to make clear the manner of establishing a complete diagram. The book is excellently printed and is well provided with marginal references to the text.

Henry Fay.

The Elements of Metallography. By Rudolf Ruer. Translated by C. H. Mathewson. First edition. New York: John Wiley & Sons. 8vo. xiv + 342 pp., ill. Cloth, $3.

The book is divided into two parts, Theory and Practice. In Part 1 there are four chapters dealing with: *One-component system*, transformations and heterogeneous equilibria. *Two-component systems*, the different cases of various solubility in the liquid and solid states, without and with polymorphous transformations or the formation of chemical compounds. The different cases are illustrated by typical alloys mostly from work done at Goettingen. Supplementary sections are given on methods of determination of equilibrium curves and methods of investigation of solidified mixtures. *Three-component systems*, insoluble in solid state; completely soluble in solid state; phase rule.

Part 2 deals with methods of thermal investigation, heating apparatus, cooling and heating curves and the like; investigation of structure, microscopic examination. At the end of the book there is a collection of references to binary fusion diagrams and an index of authors' names besides the usual index.

To those who are interested in metals and alloys, and their name is legion, this work will be very welcome. It is well written and the reader is led by easy steps through the various groups of alloys, each illustrated by diagrams, without being lost in some of the more intricate problems of physical chemistry on the way. Criticisms of the book are few. Of the few photomicrographs given some are excellent while others are indistinct. The collection of references at the end of the book is apparently incomplete, while the addition of sections on brasses and bronzes parallel to that on iron and carbon would have been of value to many general readers.

For such a book there is a great need and this one will undoubtedly be a welcome addition both for class work and the general reader.

THE JOURNAL

OF THE

American Chemical Society

SEVENTEENTH ANNUAL REPORT OF THE COMMITTEE ON ATOMIC WEIGHTS. DETERMINATIONS PUBLISHED DURING 1909.

BY F W CLARKE.

Received February 2, 1910

The year 1909 has been marked by unusual activity in the determination of atomic weights, and much of the work done was of remarkably high quality. It is also noteworthy because of the publication, in German, of the collected papers by Richards and his colleagues in Harvard University.[1] The actual work of the year, including some data from 1908, may be summarized as follows:

Chlorine and Nitrogen.—The work of Guye and Fluss[2] on nitrosyl chloride, NOCl, appeared in December, 1908, too late for recognition in the report for last year. The weighed gas was passed, first over silver, which absorbed the chlorine; then over heated copper, which fixed the oxygen; and finally over calcium, which combined with the nitrogen. A complete analysis of nitrosyl chloride was thus effected, giving direct comparisons of nitrogen and chlorine with oxygen, independent of every other atomic weight. The following data were obtained, the actual weights being given in the first four columns:

NOCl.	N.	O.	Cl.	At. wt. N.	At. wt Cl.
0.5341	0.1142	0.1305	0.2893	14.000	35.470
0.4284	0.0916	0.1046	0.2319	14.012	35.472
0.7995	0.1710	0.1954	0.4331	14.002	35.464
0.5639	0.1204	0.1375	0.3048	14.010	35.468
0.5121	0.1095	0.1251	0.2773	14.005	35.466
			Mean,	14.008	35.468

---

[1] Experimentelle Untersuchungen über Atomgewichte, von Theodore William Richards und seinen Mitarbeitern. Hamburg und Leipzig, 1909.

[2] *J. chim. phys.*, 6, 733. The table given here is abbreviated from the tables as published by Guye and Fluss.

Scheuer[1] deduces the atomic weight of chlorine from the density of gaseous hydrochloric acid. Twenty-eight determinations are given, representing weighings in six different globes. The mean of all, for the weight of a normal liter of hydrochloric acid, is 1.63941 grams. From this figure Scheuer computes, by different methods, values for Cl between 35.442 and 35.454. He concludes that the atomic weight is very near 35.45.

The density, composition by volume, and compressibility of hydrochloric acid have also been determined, with great care, by Gray and Burt.[2] Three series of density determinations are given, with gas from different sources. The following figures give the weight of one liter of hydrochloric acid, at 0°, 760 mm., and at London:

I.	II.	III.
1.64053	1.64022	1.63950
1.64004	1.63999	1.64013
1.64020	1.63976	1.63984
1.63986	1.64083	1.64069
....	1.64030	1.64031
....	1.64021	1.64017
....	1.64027	1.64050
....	....	1.64051
....	....	1.63992
....	....	1.64001

Series I and II are subject to a small correction for gas adsorbed by the walls of the glass bulbs in which the weighings were made. Series III represents weighings in "quartz" glass, and do not need the correction. The final mean, reduced to Lat. 45°, gives for the weight of the normal liter, 1.63915 grams.

In order to determine the volumetric composition of hydrochloric acid, measured volumes of it were decomposed by heated aluminum, and the volume of hydrogen liberated was also measured. From two volumes of hydrochloric acid the following volumes of hydrogen were obtained.

1.00797	1.00781
1.00795	1.00779
1.00790	1.00787
1.00790	1.00798

Mean, 1.00790. Combining this figure with that given for the density, and with Morley's value for the atomic weight of hydrogen, 1.00762, Cl = 35.459. The compressibility measurements, which are too complex for reproduction here, gave with the density determinations, by the method of limiting densities, the value Cl = 35.461. The mean value, 35.460, is adopted by the authors.

---

[1] *Compt. rend.*, 149, 599. Scheuer's complete memoir (*Z. physik. Chem.*, 68, 575) was received too late for consideration here. Scheuer discusses his own data very fully, and finally combines them with the figures given by Gray and Burt. His final conclusion is that Cl = 35.466.

[2] *J. Chem. Soc.*, 95, 1633.

Nitrogen and Silver.—A new series of analyses of ammonium chloride is due to Richards, Koethner and Tiede.[1] The results, with all corrections applied, are as follows:

Weight NH_4Cl.	Weight AgCl.	At. wt. N.
2.02087	3.41469	14.009
2.23894	5.99903	14.008
1.55284	4.16076	14.008
1.36579	3.65959	14.007
1.61939	4.33914	14.007
1.93795	5.19219	14.012
2.89057	7.74498	14.009
1.31405	3.52082	14.009
1.82091	4.87921	14.006
	Mean,	14.0085

Calculated with H = 1.0076, Cl = 35.4574, and Ag = 107.881. These values for Cl, Ag and N are obtained by combining the data given above with the ratios Ag : NO_3 and Ag : Cl as formerly determined in the Harvard Laboratory.

Iodine and Silver.—Baxter and Tilley[2] have determined the ratio between iodine pentoxide and silver. The pentoxide was first reduced, in solution, by hydrazine hydroxide, and the iodine was afterwards precipitated and weighed as silver iodide. Two series of determinations were made, one by Tilley, the other by Baxter. The results, with all corrections applied, were as follows:

SERIES I.

Weight I_2O_5.	Silver used.	Ratio.
6.06570 9.48035[3]	3.92027 6.12611	0.646234
7.73052	4.99564	0.646223
12.63909	8.16777	0.646231
9.49913	6.13841	0.646208
8.34369	5.39202	0.646239
8.83155	5.70715	0.646223
6.77487	4.37803	0.646216
	Mean,	0.646225

---

[1] This Journal, 31, 6. The actual analyses were all made by Tiede. Richards is only responsible for the methods employed in the work.

[2] This Journal, 31, 201.

[3] The first two solutions were inadvertently mixed, and hence are combined here.

SERIES II.

Weight I_2O_5.	Silver used.	Ratio.
12.09036	7.81320	0.646234
6.29744	4.06957	0.646226
10.89880	7.04309	0.646226
9.33895	6.03505	0.646222
10.15370	6.56160	0.646236
11.00453	7.11141	0.646226
7.01649	4.53431	0.646236
9.33573	6.03304	0.646231
8.72163	5 63619	0.646231
9.01524	5.82591	0.646229
	Mean,	0.646230

Combining these figures with the former determinations by Baxter of the silver-iodine ratio, the authors find, with reference to O = 16, Ag = 107.850 and I = 126.891.

Carbon.—Scott[1] has sought to determine the atomic weight of carbon by means of analyses of tetraethylammonium bromide, $C_8H_{20}NBr$. This salt was titrated against silver solutions, and the ratio so determined gave the subjoined molecular weights, when Ag = 107.93.

Weight bromide.	Weight Ag.	Mol. wt bromide.
5.07039	2.60146	210.360
5.26380	2.70142	210.305
7.10662	3.64683	210.325
6.79951	3.48976	210.293
2.72225	1.39695	210.330
6.24530	3.20481	210.326
5.74581	2.94853	210.323
5.21663	2.67699	210.321

From these figures, when NH_4Br = 97.995 and H = 1.0075, C = 12.026, a very high value. One experiment was also made with the corresponding methyl compound, of which 8.64585 grams balanced 6.05348 grams of silver. Hence, C = 12.024. With Ag = 107.88 the values become C = 12.019 and 12.017. All weights were reduced to a vacuum.

In a criticism of Scott's work, Thorpe[2] has pointed out the possibility of errors due to the vacuum reductions, errors discussed long ago by Marignac, and recently, in more detail, by Guye and Zachariades.[3] The substances analyzed were weighed in powder, under which conditions they are liable to condense and occlude air. A probable correction, applied to Scott's weighings, reduced the atomic weight of carbon to 12.008, in harmony with other good determinations. To this criticism Scott[1] published a rejoinder, seeking to show, on the basis of experimental evidence, that the supposed errors do not, in fact, exist. According to Guye and Zachariades, the errors noted by them in the study of 26 compounds may amount to as much as, or even more than, 3 parts in 10,000.

---

[1] *J. Chem. Soc.*, 95, 1200.

[2] *Proc. Chem. Soc.*, 25, 285.

[3] *Compt. rend.*, 149, 593 and 1122.

The atomic weight of carbon has also been deduced by Baumé and Perrot[2] from density determinations of methane and ethane. For methane, the following weights of the normal liter are given:

0.71688	0.71633
0.71655	0.71670
0.71631	0.71676
0.71667	0.71723
0.71749	....

From the mean, 0.7168 gram, by different methods of reduction, the authors find values for C ranging from 12.003 to 12.005.

For the normal liter of ethane the following weights were found:

I.	II.
1.35671	1.35600
1 35679	1.35610
1 35671	1.35653
1.35652	1.35640
1.35700	1.35590
1.35640	1.35640

The mean of the second series, 1.3562 grams, is preferred by the authors. Reduced by Leduc's method of molecular volumes it gives C = 11.996. By Berthelot's method of limiting densities, C = 12.004. By reduction with the critical constants C = 12.036. The results from ethane are evidently not conclusive. From the vapor density of toluene, as measured by Ramsay and Steele, Leduc[3] deduces C = 12.003.

Scott,[4] in a preliminary note, gives, without details, the results of combustions of naphthalene and cinnamic acid. In six analyses, 17.6175 grams of naphthalene gave 60.5355 of CO_2. Hence, C = 11.999. In two analyses, 8.6153 grams of cinnamic acid gave 23.0413 of CO_2. Hence, 12.0015. The cause of the discrepancy between these figures and those from the alkylammonium bromides remains to be discovered.

Phosphorus.—Ter Gazarian[5] gives the following figures for the weight of a normal liter of phosphine, PH_3.

---

[1] *Proc. Chem. Soc.*, 25, 286.

[2] *J. chim. phys.*, 7, 369; also *Compt. rend.*, 148, 39.

[3] *Compt. rend.*, 148, 832. For other papers by Leduc on atomic weights and gaseous densities see *Compt. rend.*, 148, 42 and 548.

[4] *Proc. Chem. Soc.*, 25, 310.

[5] *Compt. rend.*, 148, 1397; *J. chim. phys.*, 7, 337.

1.52955
1.52907
1.52933
1.52944
1.52907
1.52933

From the mean, 1.5293 grams, he deduces the atomic weight P = 30.906, when H = 1.008. The value found is very low.

Vanadium.—Prandtl and Bleyer[1] have redetermined the atomic weight of vanadium by analyses of carefully purified vanadyl trichloride, $VOCl_3$. The substance, after weighing, was decomposed by water, in presence of a little zinc. The latter reduced the vanadium to its lower form of oxidation, and also prevented the escape of chlorine, either as free element or as oxides. In the filtrate from the solution the chlorine was determined as silver chloride. Two series are given, with vacuum weights, as follows:

I.

Weight $VOCl_3$.	Weight AgCl.	Ratio.
5.47218	13.54724	40.393
5.85234	14.50771	40.346
3.23175	8.00636	40.365
5.24732	13.01359	40.322
3.56589	8.83375	40.367

Hence, rejecting the first analysis, V = 51.133.

II.

Weight $VOCl_3$.	Weight AgCl.	Ratio.
4.91432	12.18494	40.331
3.64470	9.04685	40.287
4.96088	12.30438	40.318
6.46766	16.04292	40.315
4.33158	10.74624	40.308
4.05060	10.04498	40.325

Hence, V = 50.963. Mean of both series, 50.048, when Ag = 107.88 and Cl = 35.46.

Arsenic.—Baxter and Coffin,[2] by analyses of silver arsenate, have redetermined the atomic weight of arsenic. Two essentially distinct methods were employed. First, the arsenate was heated in gaseous hydrochloric acid, and so converted into silver chloride. Secondly, the arsenate was dissolved in nitric acid, and the silver was then precipitated, with the usual precautions, either as chloride or as bromide. Six series of results are given, which, with all corrections applied, are as follows:

---

[1] *Z. anorg. Chem.*, 65, 152.

[2] This Journal, 31, 297.

I —FIRST METHOD

Weight arsenate	Weight AgCl	Ratio
3 17276	2 94922	0 929544
2 65042	2 46367	0 929539
3 51128	3 26396	0 929564
5 83614	5 42503	0 929558
5 72252	5 31947	0 929568

II —SECOND METHOD

4 59149	4 26796	0 929537
3 38270	3 14436	0 929542
	Mean, Series I and II,	0 929550

III —SECOND METHOD

Weight arsenate	Weight AgBr	Ratio
8 75751	10 66553	1 21787
6 76988	8 24545	1 21796
5 19424	6 32590	1 21787
5 33914	6 50258	1 21791
8 24054	10 03552	1 21782
7 57962	9 23147	1 21793
6 05230	7 37106	1 21789

IV —FIRST METHOD

Weight arsenate	Weight AgCl	Ratio
4 67268	4 34389	0 929636
7 71882	7 17597	0 929672
5 28049	4 90908	0 929664
4 25346	3 95424	0 929652
3 47340	3 22893	0 929616
5 17269	4 80879	0 929650
4 10766	3 81858	0 929624

V —SECOND METHOD.

5 47133	5 08643	0 929652
	Mean, Series IV and V,	0 929646

VI.—SECOND METHOD

Weight arsenate.	Weight AgBr	Ratio
4.96261	6 04440	1 217988
5 31743	6 47658	1 217991
4.46882	5 44300	1 217995
4 16702	5 07539	1 217990

Series I, II and III are in close agreement, and Series IV, V and VI agree also; but the two groups differ, because of differences in the samples of arsenate employed. The first group is preferred, and gives, in mean, when Ag = 107.88, As = 74.957.

Chromium.—Two memoirs upon the atomic weight of chromium have been issued from the Harvard Laboratory. Baxter, Mueller and Hines[1] analyzed pure silver chromate, by dissolving the salt in dilute nitric acid, and after reducing the chromium to the chromic state, either by sulphur dioxide or by hydrazine sulphate, precipitating the silver as chloride or bromide. Two series of results are given, as follows; with all corrections applied.

---

[1] This Journal, 31, 529.

I.—CHLORIDE SERIES.

Weight chromate.	Weight AgCl.	Ratio.
10.30985	8.90908	0.864132
8.26920	7.14492	0.864040
6.56679	5.67444	0.864111
	Mean,	0.864094

II.—BROMIDE SERIES.

Weight chromate.	Weight AgBr.	Ratio.
2.63788	2.98621	1.13205
2.82753	3.20084	1.13203
2.33454	2.64268	1.13199
1.77910	2.01402	1.13204
2.33198	2.63994	1.13206
3.10402	3.51390	1.13205
2.92751	3.31427	1.13211
4.21999	4.77762	1.13214
5.24815	5.94104	1.13203
6.24014	7.06484	1.13216
7.923-3	8.96982	1.13211
	Mean,	1.13207

Using the silver-chlorine ratio of Richards and Wells, and the silver-bromine ratio of Baxter, these determinations give 65.0333 as the percentage of silver in Ag_2CrO_4. Hence, if Ag = 107.88, Cr = 52.008.

The second memoir, by Baxter and Jesse,[1] relates to analyses of silver dichromate, by essentially the same methods as those used in the previous investigation. The corrected results are subjoined.

Weight dichromate.	Weight AgBr.	Ratio.
5.71554	4.97149	0.869820
4.87301	4.23888	0.869869
7.45476	6.48425	0.869813
4.75269	4.13420	0.869865
8.15615	7.09495	0.869890
6.15412	5.35309	0.869839
6.83662	5.94678	0.869842
5.39883	4.69631	0.869876

In a single experiment, 6.26657 grams of the dichromate gave 4.16076 of silver chloride. From all of the data, the percentage of silver in $Ag_2Cr_2O_7$ is 49.9692. Hence, with Ag = 107.88, Cr = 52.013. The rounded-off value 52.01 is adopted.

Tellurium.—A new method for detaining the atomic weight of tellurium has been adopted by Lenher.[1] The double bromide, K_2TeBr_6, was converted into KCl by first heating in chlorine, and afterwards in gaseous hydrochloric acid. The determinations were made with tellurium from three widely different sources, and calculated with Cl = 35.46, Br = 79.92, and K = 39.095. All weights were reduced to a vacuum. The results obtained, in three series, were as follows:

---

[1] THIS JOURNAL, 31, 541.

Weight K_2TeBr_6.	Weight KCl	At. wt. Te.
	I.	
2.33360	0.50779	127.54
1.27372	0.27716	127.54
1.47573	0.32111	127.56
1.65715	0.36059	127.55
1.54006	0.33513	127.5
	II.	
1 82810	0.39778	127.56
1 87342	0.40765	127.55
1.48045	0.32214	127.55
2.24775	0.48911	127 54
	III.	
Weight K_2TeBr_6.	Weight KCl.	At wt. Te.
2 37899	0.51767	127.54
1 79926	0.39146	127.64
0 94102	0.20476	127 56
1.55357	0.33806	127.54
1 95038	0.42440	127.54
1 73248	0.37698	127.5
1 81923	0.39586	127.55

Mean of all as one series, Te = 127.55.

Lenher's researches, like those of several previous investigators, have had in view the determination of the homogeneity of tellurium, a conclusion which seemed to be finally established. Browning and Flint,[2] however, by a special process of fractionation, believe that they have strong evidence in favor of the view that tellurium is complex. When tellurium tetrachloride is decomposed by water, part of the tellurium is precipitated as TeO_2 and part remains in solution, to be recovered by subsequent treatment with ammonia and acetic acid. These two portions, converted into basic nitrate of tellurium, gave different values for the atomic weight of the element. From the first precipitate, Te = 126.49 in mean, and from the second Te = 128.85. The investigation is to be continued.

Mercury.—Preliminary determinations of the atomic weight of mercury have been published by Easley.[3] First, mercuric chloride was reduced by a well-known reaction with hydrogen peroxide. The mercury was collected mainly in a globule, but a small part of it which remained disseminated, was redissolved and determined electrolytically. With vacuum reduction the results obtained were as follows:

[2] *Am. J. Sci.*, [4] 28, 347.

[3] THIS JOURNAL, 31, 1207.

Weight $HgCl_2$.	Weight Hg.	At wt Hg
23.43239	17.30826	200.44
12.59751	9.30608	200.52
10.94042	8.08134	200.46
11 73734	8.67044	200.50
	Mean,	200 48

Secondly, mercury was removed from the chloride as in the preceding experiments, and the chlorine in the filtrate was precipitated and weighed as silver chloride, with all the known precautions. The corrected data are as follows:

Weight $HgCl_2$	Weight AgCl	At wt. Hg.
10.50276	11 08744	200.64
9.03634	9.54027	200.62
23.43239	24.73606	200 65
10.94042	11 55158	200 59
11 11409	11 73470	200 60
16.63910	17.56808	200 60
	Mean,	200.62

Calculated with Ag = 107.88 and Cl = 35.46. Easley regards the second series as the more trustworthy. The investigation is to be continued by other methods.

Rhodium.—Two inaugural dissertations on the atomic weight of rhodium have appeared from Gutbier's laboratory at Erlangen. Renz reduced the rhodium pentamine bromide, $Rh(NH_3)_5Br_3$, in hydrogen, and cooled the remaining metal in an atmosphere of carbon dioxide. With H = 1.008, N = 14.01, and Br = 79.92 and vacuum weights, the subjoined results were obtained.

Weight bromide.	Weight Rh.	At wt Rh.
0.87624	0.21057	102.784
1.56500	0.37638	102.980
2.04033	0.49069	102.888
2.00120	0.48135	102.908
1.89278	0.45525	102.901
2.30210	0.55416	103.014
1.02065	0 24555	102.937
1.31485	0.31622	102.890
1.86060	0.44766	102.947
1.51040	0.36339	102.942
	Mean,	102.919

H. Dittmar's dissertation deals with the corresponding chloride,

$Rh(NH_3)_6Cl_3$, by essentially the same method as that of Renz. With vacuum weights and Cl = 35.46, the following results are given:[1]

Weight chloride	Weight Rh.	At. wt Rh
2.01526	0.70465	102.987
1.83589	0.64173	102.937
1.57210	0.54934	102.884
2.17528	0.76046	102.955
2.03911	0.71271	102.925
2.20000	0.76890	102.916
1.02840	0.35941	102.908
	Mean,	102.930

Palladium.—Gutbier, Haas and Gebhardt[2] have redetermined the atomic weight of palladium by analyses of palladosamine bromide, $PdN_2H_6Br_2$. Two series of reductions in hydrogen are given, with vacuum weights, and H = 1.008, N = 14.01, and Br = 79.92 for the antecedent value.

I

Weight bromide	Weight Pd	At. wt. Pd.
0.54402	0.19286	106.495

[1] Dittmar's work has also appeared in *Sitzungsb. phys. Med. Soz. Erlangen*, 40, 184.

[2] *J. prakt. Chem.*, [2] 79, 457. This includes the thesis work of Haas cited in my 1908 report. Gutbier has also published the thesis work of Krell and Woernle, *J. prakt. Chem.*, 79, 235. The data are already given in previous reports of this committee.

The authors reject some of the determinations, and conclude that Pd = 106.689 is the most probable value.

Iridium.—In a preliminary notice presented to the British Association for the Advancement of Science, Archibald[1] states that analyses of potassium chloroiridate give the atomic weight Ir = 192.90. The investigation is not completed, and no details are published.

Platinum.—A very elaborate memoir on the atomic weight of platinum is also due to Archibald.[2] The chloroplatinates and bromoplatinates of potassium and ammonium were analyzed, with all known precautions, and many ratios were so determined. The platinum itself was weighed, and also the silver and silver halide corresponding to the halogens in the several salts. In the analyses of the potassium compound the chlorine or bromine determinations were made in two portions, giving the halogen corresponding to the platinum, that is, the part lost on ignition in hydrogen, or four atoms, and that belonging to the potassium, two atoms.

The actual data relative to the weighings, and the individual determinations of atomic weight, are unfortunately too voluminous to be reproduced here. The mean results given by the various ratios are as follows:

FROM K_2PtCl_6 (14 ANALYSES).

Ratio	$K_2Cl_6 : Pt$	Pt = 195.23
"	$4AgCl : Pt$	195.21
"	$2AgCl : Pt$	195.24
"	$4AgCl : K_2PtCl_6$	195.20
"	$2AgCl : K_2PtCl_6$	195.24
"	$4Ag : Pt$	195.22
"	$2Ag : Pt$	195.23
"	$4Ag : K_2PtCl_6$	195.19
"	$2Ag : K_2PtCl_6$	195.22

FROM $(NH_4)_2PtCl_6$ (5 ANALYSES).

Ratio	$(NH_4)_2PtCl_6 : Pt$	Pt = 195.21
"	$6AgCl : Pt$	195.22
"	$6AgCl : (NH_4)_2PtCl_6$	195.23
"	$6Ag : Pt$	195.22
"	$6Ag : (NH_4)_2PtCl_6$	195.24

FROM $(NH_4)_2PtBr_6$ (3 ANALYSES).

Ratio	$(NH_4)_2PtBr_6 : Pt$	Pt = 195.25
"	$6AgBr : Pt$	195.22
"	$6AgBr : (NH_4)_2PtBr_6$	195.23
"	$6Ag : Pt$	195.21
"	$6Ag : (NH_4)_2PtBr_6$	195.22

FROM K_2PtBr_6 (6 ANALYSES).

Ratio	$K_2Br_6 : Pt$	Pt = 195.21
"	$4AgBr : Pt$	195.23

---

[1] *Chem. News*, 100, 150.

[2] *Proc. Roy. Soc. Edinburgh*, 29, 721.

Ratio $2AgBr : Pt$	Pt = 195.22
" $4AgBr : K_2PtBr_6$	195.21
" $2AgBr : K_2PtBr_6$	195.22
" $4Ag : Pt$	195.22
" $2Ag : Pt$	195.23
" $4Ag : K_2PtBr_6$	195.20
" $2Ag : K_2PtBr_6$	195.20

The arithmetical mean of these 28 ratios gives Pt = 195.22. Archibald, however, prefers to reject those which involve the weights of the original salts, using only 12 ratios. Mean, Pt = 195.23. This work evidently supplants all previous work on the atomic weight of platinum.

Radium.—From relationships between the wave-lengths of the spectral lines Watts[1] finds Ra = 226.56. Other atomic weights computed with that of radium are Mg, 24.32; Ca, 40.08; Sr, 87.62; and Ba, 137.41.

For the gaseous emanation of radium, by studying its physical properties, Gray and Ramsay[2] find a probable atomic weight of Em = 176. This conclusion, however, is not a finality.

Miscellaneous Notes.—Guye and Tsakalotos[3] have studied the determination of water of crystallization as a means of determining atomic weights. The substance investigated was barium chloride, but the results obtained, regarded as atomic weight determinations, were not satisfactory. Guye[4] has also discussed the variations from the law of Avogadro, and in another paper,[5] the general subject of atomic weight determinations by physical methods. A revision of the atomic weights of the rare earth metals is due to Urbain.[6] In a series of papers, not yet completed, Dubreuil[7] has undertaken to recalculate, by a peculiar mathematical method, the atomic weight determinations of Stas.

Mathematical relations between the atomic weights have been studied by Bernoulli,[8] Delaunay and Garnier,[9] Egerton,[10] Loring,[11] and Moir.[12] Hinrichs has also published a summary of his views regarding atomic weights,[13] and also several papers upon his method of calculation.[14]

[CONTRIBUTION FROM THE CHEMICAL LABORATORY OF HARVARD COLLEGE.]

THE HEATS OF COMBUSTION OF THE OCTANES AND XYLENES.

BY THEODORE WILLIAM RICHARDS AND RICHARD HENRY JESSE, JR

Received January 10, 1910.

Julius Thomsen sought, long ago, to obtain clues concerning the constitution of organic substances from the comparison of their heats of combustion. This endeavor, although it failed of a wholly satisfactory outcome, nevertheless showed certain relationships between the several members of homologous series and unmistakable differences due to variations in structure. Enough regularity is manifested in these results to show that the idea is worthy of further study.

The first step is obviously to seek among the older results for possible causes of the incompleteness in the relationships. This may be due either to the inadequacy of the theory or to the imperfection of the experiments. Turning to the first, one must admit at once that the heat of formation does not exactly represent the free energy of the change involved in the building up of the substance from other constituent elements; and therefore that it cannot represent the work which may actually be done by the chemical affinity. Yet nevertheless because in most cases where aqueous solutions are not concerned, free energy change is not very far from total energy change, a close relationship would be expected; moreover not only the free energy but also the bound energy must be supposed to have some relation to chemical structure. Hence if each of its constituents has a precisely regulated magnitude, the total energy change itself should be significant, although its significance might not be so easy to interpret as if it were simpler in its nature.

On the other hand, the experimental part of Thomsen's investigations was, as is well known, not wholly satisfactory and was undoubtedly inadequate in many cases. His universal burner gave too high results with all liquids having boiling points much above room temperatures, and the higher the boiling point the greater was the error. On the other hand, the results of Berthelot and Stohmann were probably too low in the cases of the more volatile liquids, because in these cases some of the liquids undoubtedly failed to burn. Hence, without further light upon the subject, one would be inclined to give more weight to Thomsen's figures with the lower-boiling substances and to shift the weight gradually over to Berthelot's and Stohmann's, as the boiling point rises. Compromises of this sort, however, cannot but be unsatisfactory; and the facts point clearly toward the need of further experimental work free from the inaccuracies of that now available. The precision needed is indeed of a high order, for differences of structure often cause but slight variations in the total magnitude of the heat of combustion of the substances; and upon these slight variations the inference wholly depends.

For example, it will be seen later that the greatest deviation between the heats of combustion of various octanes is no greater than one-third of one per cent. and if the magnitude of the variation is to be certain within one-tenth of its value, the several observations must be determined to within less than two one-hundredths of one per cent., a degree of precision which has never been approached in thermochemical work of this kind.

It was with the hope of obtaining more precise knowledge of these important quantities that E. Fischer and Wrede,[1] in Berlin, and Richards, Henderson and Frevert, in Cambridge, began the revision of thermochemical data, using quite different methods, which seem to give about equally reliable results. The German experimenters used the electrical resistance thermometer and comparatively small temperature changes, applying the usual correction for cooling. On the other hand, the American experimenters contented themselves with good mercury thermometers and arranged the conditions so that these thermometers could be read with precision and could yield sufficiently accurate results, eliminating the cooling correction by causing the environment of the calorimeter to change in temperature at the same rate as the inner vessel itself. Both groups of experimenters have attempted only to determine a comparatively small number of a few typical substances. The work of revising the data is therefore only at its very beginning.

The present research consists of a continuation of the earlier Cambridge work. The method used in that work was chosen for the continuation because it is much more speedy in execution than that used in Germany. The electrical thermometer, admirable as it is in many respects, is an exceedingly complicated instrument, and the calculation of a single temperature from the observed data requires much patience. The complete calculation of a single calorimetric determination by this method requires several hours. This is in addition to the laborious preparation, and adjustment of the sensitive electrical instrument. On the other hand, the adiabatic Harvard method is simple in the extreme. The temperature change is read off from the thermometers at once and the only corrections which have to be applied are those easily calculated figures which give the error of the mercury thermometer at each reading. The correction for cooling is non-existent. Hence it is easily possible for a single experimenter by the Harvard method to conduct and calculate three determinations in a single day, whereas it would hardly be possible for him to do more than one a day by the more elaborate method. If this more elaborate method yielded more accurate results, the difference in time ought not seriously to influence the experimenter, but because apparently the range of error is about the same in both cases, the advantage of the quicker method is very obvious.

---

[1] Fischer and Wrede, *Kgl. Preuse, Acad. Sitzber.*, 19, 20, 21, 687 (1904). An important correction of the detail is to be found in *Z. physik. Chem.*, 53, 161 (1903).

The object of the research and the method of attack having thus been clearly outlined, it becomes necessary to justify the selection of the individual substances to be chosen for experimentation. Obviously the compounds should be complex enough to allow of considerable differences in structure and yet, on the other hand, not so complex as to complicate too greatly the interpretation of the results. The theoretical problem is greatly simplified by avoiding the presence of more than two elements Moreover the compounds should be capable of being prepared in a state of very great purity, free from other substances which could seriously influence their heats of combustion. Among the incalculable number of organic compounds, these deciding criteria narrow greatly the range of choice; and from the theoretical point of view there seemed to be no question that the simpler hydrocarbons are the compounds most suitable to serve as a starting point Among these the octanes seemed to be, on the whole, the best, because their molecular complexity is enough to allow of great variety of arrangement, but not so great as to confuse the relationships. The difficulty of obtaining them in a pure state seemed in the first place to be a serious barrier, but Dr. Latham Clarke, during the summer of 1906, kindly undertook the working out of methods for this purpose. He became greatly interested in the problem from the point of view of organic synthesis and was able, in the course of several years, to prepare larger quantities than had ever been made before of these hydrocarbons and of great purity. Most of those which he prepared had indeed never been isolated by previous experimenters. It is our hope that in the course of time all of the isomeric octanes may be prepared and investigated. The present paper contains results for only five, the others having not yet been prepared in sufficient quantities for calorimetric experiments.

In order to refer the determinations to a satisfactory and perfectly definite standard, under the somewhat new conditions involved in this new series of experiments, it was desirable to repeat the determinations made with sugar and benzene by Richards, Henderson and Frevert, in the research already mentioned. These two substances serve admirably for calorimetric standards because they are so easily obtained in a pure state. They typify respectively the solid and the volatile liquid; methods which will serve for these two substances can easily be made to serve for most others among the combustible organic substances. As will be seen, the value obtained by the earlier experimenters for sugar was confirmed, and the anomalies in the combustion of benzene have been explained and corrected so that for this substance yet more satisfactory results are to be chronicled than were reported in the earlier paper.

The investigation showed that not only must the substance be confined in flexible glass bulbs, but that special pains must be taken with regard to the form of the containing capsule and the details of manipulation in order to insure complete burning. When the proper conditions have been established, the presence of nitrogen in the compressed gas of the bomb does not prevent the complete combustion of the hydrocarbon. It will be seen that the results finally obtained showed a very satisfactory agreement among themselves. Without the high degree of precision made possible by the devices to be described, the data could not have been accurate enough to form the basis of any important conclusions; because, as has been said, the variations from which inferences must be drawn are small in proportion to the total magnitude to be measured.

Apparatus.

During the first part of the work the adiabatic calorimeter was essentially like that used by Richards, Henderson and Frevert.[1] It consisted of a large silver calorimeter holding about 4 4 liters, in which was immersed the calorimetric bomb. This was surrounded below and on all sides by a jacketed vessel and covered with a copper pan. Both of these receptacles contained alkali to which acid was added in order that the temperature of the surroundings of the calorimeter should keep pace with that of the calorimeter itself. The temperature of this solution was easily and quickly changed. The air space between the silver calorimeter and the copper jacket was made as small as possible, the two vessels being insulated thermally from one another by pieces of cork. The complete insulation was tested electrically just before each experiment. The first diagram (Fig. 1), taken from the earlier paper, depicts the arrangement in section.

The method of carrying out the determinations was so nearly similar to those described in the earlier paper that details are unnecessary. In one essential point, however, an alteration was introduced, namely as to the rate of stirring. On account of the experience recently gained in other thermochemical work in the laboratory (namely that carried out by Dr. L. L. Burgess and one of us concerning the heat of solution of metals),[2] the agitation of the liquid in the calorimeter was more thorough than in the earlier experiments. On this account a correction had to be determined and applied for the heat gained through friction. This correction will be discussed later.

In the later experiments the method of jacketing the calorimeter was modified in a fashion which greatly increased the convenience of experimentation. It may be remembered that Richards and Forbes[3] made calorimetric determinations of the heat of amalgamation of metals in a

calorimeter wholly enclosed in a single jacketing vessel, which was immersed below the surface of the liquid in the outer vessel Dr. F. Wrede suggested the extension of the use of this kind of calorimeter for the bomb also The obvious advantage of having only one jacketing vessel to regulate in temperature was found practically to outweigh the difficulty in keeping the apparatus water-tight. We succeeded in arranging the other experimental details so that this method of completely immersing the can surrounding the calorimeter will always be used in the future, in preference to the older apparatus involving a separate lower vessel and a movable pan above The second diagram (Fig 2) represents the arrangement.

A brief description of the essential features of the new apparatus is in place. To the top of the inner copper can C was soldered a flat projecting flange of copper of the same thickness as the can itself, and to the under edge of this flange was soldered a ring made from rectangular brass rod 1/8 inch thick ar[illegible] inch high. As may b[illegible] figure, this r[illegible] from the s[illegible] ear[illegible] any possible thermal lag of the heavier mass of metal does not affect the inner vessel. The cover to this can consisted of a circular piece of sheet copper bearing tubes for the thermometer and stirrer and having on its upper edge a brass ring similar to the one soldered beneath the flange. When the calorimeter and its contents had been placed in the vessel (C), the cover was put on and a gasket of black sheet rubber was placed between the flange and the edge of the cover. These were then clamped together by means of several small brass clamps, sealing the can perfectly water-

tight. The whole arrangement was then completely submerged in the alkaline liquid in the outer vessel. With this arrangement one burette only is necessary, and only two thermometers must be compared. Determinations on sugar with this apparatus gave results identical with those obtained by the use of the older apparatus; that is to say, the advantage of this new form consists not so much in increased accuracy as in greater ease of operation.[1]

For accurate work the temperature of the outer jacket must be kept within 0 1° of that in the calorimeter. In following the rise, the acid was introduced in the immediate neighborhood of a rotary triple propeller driven by an electric motor at the rate of about 250 revolutions a minute. In this way equilibrium was established throughout the whole outer bath within a few seconds after the introduction of a quantity of acid. The sulphuric acid was run into the outer jacket (and into the cover also, in the earlier experiments) from the burettes graduated in terms of the volume of acid necessary to raise the vessels and their content 0.1°. The temperatures were observed at the same time by the thermometers.

As may readily be seen from the above description, the operator of the earlier form of apparatus was compelled at the same time to manipulate two burettes and to read the three thermometers in the calorimeter, the outer vessel and the cover. Since there was generally a rise of about 2° in the two minutes following the combustion, this requires rapid reading and manipulation; nevertheless, after some experience has been acquired, the task is not nearly so difficult as might at first sight be supposed. The second form of apparatus, in which the calorimeter was wholly beneath the solution in the larger vessel, does away with one burette and one thermometer.

The inner vessel (C) which held the calorimeter proper was in each case a can of heavy copper, nickel-plated and well burnished on the inside. Its walls were about of the same thickness as those of the silver calorimeter, so that the lag in heating each might be approximately the same. It was supported by metallic legs 5 centimeters high, so that there was plenty of room for the circulation of the alkaline solution beneath it.

The calorimeter itself (D) was a can of spun silver, 1357 g. in weight and of 4432 cc. capacity. It was placed within the can (C) and was insulated from it by pieces of cork. In the older form of apparatus, the air space between the silver and the nickel surface was about 3 millimeters thick; in the later form it was about 5 millimeters thick. The complete insulation was tested electrically before each calorimetric experiment.

---

[1] Of the experiments recorded in this paper, those marked experiments 7–11 and 30–45, inclusive, were made with this "submarine" form of apparatus; all the others were made with the older form.

The bomb was the one used by Richards, Henderson and Frevert. It was of the Atwater type, made by Singleton and Dinsmore, Middletown, Connecticut.[1] The inside of the bomb and the bottom of the cover were lined with spun platinum. To prevent possible heat effects from the oxidation of the lead gasket (used for sealing the bomb) during combustion, Richards, Henderson and Frevert protected the gasket by means of strips of gold foil.[2] In the earlier stages of the present work also, this method was used, but the accurate fitting of the gold strips is a tedious task, and, moreover, when the task was completed, it was necessary to use great force to screw down the top of the bomb sufficiently to prevent leakage. It was finally found that heavily gold-plated gaskets would answer the purpose. The gaskets were given three coats of gold, each coat being well burnished before the next was applied. The coating was not enough wholly to prevent oxidation, but the amount oxidized in a single determination was not enough to affect the heat of combustion appreciably. This was shown by the fact that the results of determinations on sugar with the gaskets protected by gold foil agreed well within the experimental error with those made with the gold-plated gaskets.

Instead of the capsule generally used for holding the substance to be burned, platinum crucibles were substituted. At first a larger crucible weighing 16 grams was used, but later it was found desirable to substitute a smaller crucible weighing 6 grams. The differences in heat capacity caused by this and other slight changes in the system were duly considered in the calculation.

Two thermometers were used for this work, both of the Beckmann type, graduated to 0.01°. One had been made by Fuess, and had a bulb containing about 75 grams of mercury and a very wide thread. The other was from Goetze, and had a smaller bulb and a narrower thread. Both were carefully standardized by comparison with two Baudin thermometers which had been calibrated by the French Bureau des Poids et Mèsures. The thermometers were also compared with two other thermometers of the Beckmann type which had also been separately standardized against the Baudin thermometers. The agreement was excellent. The Fuess thermometer had been standardized by the German Physikalisch-Technische Reichsanstalt, and this verdict agreed with the comparison with the French thermometers. No difference in the results obtained by the two thermometers could be detected.

The thermometers were standardized and all the determinations were made in a room provided with such regulating devices that the temperature could be kept very constant. Therefore no corrections are necessary for effects of differences in room temperature on the projecting threads of the thermometers.

---

[1] Atwater and Snell, THIS JOURNAL, 25, 659 (1903).

[2] For details, see Richards, Henderson and Frevert, *Loc. cit.*, p. 576.

The oxygen used was supplied by the Linde Air Products Company, of Niagara Falls. It had been obtained from liquid air, and was free from carbon dioxide and from chlorine. Samples of each tank used were analyzed volumetrically for oxygen. The purity ranged in general from 97.5 per cent. to 98.2 per cent. of oxygen.

The Heat of Combustion of Sugar.

Two of the samples of sugar prepared for the work of Richards, Henderson and Frevert were still available for this work. These samples had been crystallized with all the necessary precautions: one (Sample A) from water, and the other (Sample B) from a mixture of water and ethyl alcohol of such proportions that the heat of combustion of the mixture was the same, gram for gram, as that of sugar itself. The concordance of the determinations on these two samples showed that not enough water was included in the crystals to be detected by thermochemical means.

The details of a combustion of sugar will serve to illustrate the method. The manipulation was similar except in a few minor points for the other substances burned.

About two grams of sugar in powdered form were weighed into the platinum crucible, and the crucible was placed on its support. This support consisted of a platinum ring attached to a heavy platinum wire projecting downward from the cover of the bomb and in metallic contact with it. Between this wire and a similar one, insulated from the bomb, was suspended a coil of fine iron wire, of measured length, the bottom of which just dipped into the sugar. If this wire is protected from the oxygen by being buried too deeply in the sugar, it is sometimes difficult to ignite the sugar by the passing of an electric current. In order to avoid a correction for the evaporation of water formed during the combustion, a little water, less than a cubic centimeter, was placed in the bomb. The cover was now placed on the bomb, and the latter was sealed by screwing down the steel cover-cap. In the earlier experiments, oxygen was run in until the gauge registered 35 atmospheres; later, as will be seen, a lower pressure was employed.

The water for the calorimeter was measured in a graduated flask, delivering a definite amount of water at 20°, and brought to the temperature at which it was desired to start the experiment. The alkaline solution in the jacket and the cover were adjusted to the same temperature. The bomb was placed in the calorimeter, and two insulated copper wires for the introduction of the electric current were attached to the platinum wires from which the fine iron coil was suspended. After the water had been poured into the calorimeter, the cover was put in place. The well-insulated electric connecting wires passed through the copper tubes in the cover provided for the wires of the calorimeter stirrer. When the thermometer and burettes were in place, the stirrers were started and the temperatures of calorimeter, jacket, and cover were equalized to within 0.01°. Readings were made every minute with the aid of a good hand lens, the thermometer being tapped by an electric vibrator immediately before each reading. When constancy had been obtained, the electric circuit was completed and the burning of the iron wire caused the combustion of the sugar. During the first rapid rise the temperatures of the outer vessels were kept from 0.05–0.1° higher than that of the calorimeter. This was done because the thermometer in the calorimeter had a slightly geater lag than that outside, and also in order to give time for the complete distribution of the heat in the jacket and cover. Richards and Burgess have shown that it is safer to keep the outer jacket a little too warm than a little too cold.[1] After the first two minutes the rise was very nearly complete and the temperatures were adjusted to within one or two hundredths of a degree. In five or six minutes the maximum temperature was reached, although readings were continued several minutes longer.

The stirring (at the rate of 68–74 strokes per minute) was much more energetic than in previous work, and caused a slight warming effect. In two blank trials of 30 and 40 minutes respectively the heating effect for 10 minutes was 0.0030° and 0.0033° with an average of 0.0031°. Thus, for experiments which lasted 7 or 8 minutes after the combustion was started, a correction of —0.002° was subtracted from the observed rise, and in those others which took 9 or 10 minutes the correction applied was —0.003°.

One centimeter of the iron wire weighed 0.00194 gram. The water equivalent of the system having been about 3760 grams, the rise due to the burning of 1 centimeter was calculated, from the heat of combustion of iron to the magnetic oxide, to be 0.0009°. Probably some ferric oxide forms also, augmenting this value slightly. The electrical heat needed to raise 1 centimeter of the wire to the point of combustion (perhaps 800°)[2] must have been enough to raise the calorimetric system through approximately an additional amount of about 0.00005°, so that the total amount to be subtracted from the thermometer reading for each centimeter of wire was approximately 0.001°, allowing for the small amount of electrical heat which must have been generated in other parts of the apparatus. This was verified by four experiments in which no sugar was burned, the combustion of the usual length of wire changing the temperature of the system 0.014°, 0.014°, 0.015°, and 0.015°, respectively, results very closely in agreement with the calculated value.

---

[1] *Loc. cit.*, in press.

[2] Fischer and Wrede assumed 600° as the temperature of ignition. *Z. physik. Chem.*, *Arrhenius Jubelband*, 69, 233 (1909).

After an experiment was ended and the gas had been allowed to escape, the interior of the bomb was carefully inspected for indications of incomplete combustion. No carbonaceous matter was found, except in a single preliminary experiment. This determination was, of course, rejected. No tests were made for carbon monoxide, since Richards, Henderson and Frevert found no traces of this gas upon repeated analyses.

A degree of acidity in the water in the bomb after combustion, capable of being neutralized by 4.0 cubic centimeters of a certain alkaline solution, indicated a quantity of nitric acid whose heat of formation must have raised the calorimeter 0.001°.[1] Corrections were duly made for this source of error.[2]

The following table records the results of a preliminary series of combustions. In these experiments the conditions were identical with those just detailed, the heat capacity being exactly the same, equivalent to about 3760 grams of water, and the same thermometer being used. Thus all the figures in the final column are comparable with one another and with the results of Richards, Henderson, and Frevert, where the same heat capacity was used, except for the fact that in the present case the weight of the sugar was reduced to the vacuum standard.

COMBUSTION OF SUGAR.

Preliminary Series.

Expt. No.	Weight sugar (in vacuum). Gram.	Observed rise of temperature (corrected for thermom. errors).	Correction for stirring.	Correction for iron wire burning.	Correction for HNO_3 formed.	Corrected rise due to sugar.	Corrected rise in temperature per gram sugar.
1	1.7577	1.868°	—0.002°	—0.015°	—0.003°	+1.848°	1.051°
2	2.0796	2.213	—0.002	—0.023	—0.004	+2.184	1.050
3	1.8473	1.964	—0.003	—0.015	—0.003	+1.943	1.052
4	1.9460	2.071	—0.003	—0.015	—0.004	+2.049	1.053
5	2.1769	2.306	—0.002	—0.015	—0.002	+2.287	1.050

The average rise of temperature in this calorimetric system for the combustion of 1 gram of sugar is thus 1.0512. For the same system, Richards, Henderson and Frevert found 1.0504 (or 1.0498, if allowance is made for the correction of the weight of sugar to vacuum, as has been done in the present calculation). The difference, about 0.13 per cent., is a small deviation, but one nevertheless greater than the probable accidental error of either average. A slight constant error is indicated; we are inclined to think that this may lie in the fact that in these later determinations the stirring of the calorimetric solution was far more rapid than in the earlier ones. The work of Richards and Burgess has shown that unless the agitation of the solution is so great that the rise of temperature of the solution is equably distributed throughout the whole calorimeter, a thermometer placed near the bottom of the calorimeter will register a temperature below the average value. Therefore the environment will not be kept warm enough, and some heat will be lost. The error thus caused is just about of the same magnitude indicated by the difference between the two series of experiments, and of course the later ones are far more trustworthy because this cause of uncertainty was removed. Incidentally it may be noted that this cause is by no means peculiar to the adiabatic method of calorimetry. It affects the cooling correction calculated by the Regnault-Pfaundler method quite as much as it affects the actual reading of the thermometer in the adiabatic method. Hence it is probable that in most calorimetric work the liquid has not been adequately stirred.

---

[1] The standardization of this solution was effected by the use of Thomsen's equation, $2N + 5O + H_2O + Aq = 2HNO_3Aq_3 + 29.8$ cal., assuming the heat capacity of the system to be equivalent to 3,760 grams of water.

[2] During the rise of about 2° enough water is evaporated to raise the aqueous pressure of the confined air space immediately above the surface of the water by 2 mm. of mercury. This causes a cooling effect in the neighborhood of 0.001°, an amount entirely negligible.

The proportions of water and metal in our calorimetric system were such that for temperatures between 0°–30° the decrease in the specific heat of water with rising temperature is about offset by the increase of the specific heat of the metal parts. Therefore there is little error in this respect in comparing the results of the present determinations done between 17.7–20.2° (at an average temperature of 19°) with those of Richards, Henderson, and Frevert, performed at an average temperature of 21.4°. Indeed it has been calculated with a good degree of approximation that the heat capacity of the system at 25° differed by less than 0.03 per cent. from that at 20°.

After the experience had been gained by the conduct of these preliminary determinations, liquids were studied, especially benzene and a number of esters. In the course of this work much further experience in calorimetry was gained, and in particular it was found that a smaller crucible was far more satisfactory than that of the large size. Accordingly, because sugar is a substance of great importance as a standard of reference, it was thought worth while to make another series with sugar, in which all the experience gained in the course of the work came into play. In this series of six determinations the heat capacity of the system had been somewhat less than in the preliminary experiments, because 10.5 grams of steel had been cut off the bomb in providing new holes to engage the spanner, 10 grams of platinum had been removed in substituting a smaller platinum crucible, and 9.2 grams less water were used in the calorimeter. The water equivalent of these changes amounted in all to 10.73 grams (which was 0.29 per cent. of the total water equivalent), and this system was used in the first two experiments recorded in the series given below. The other four involved a still somewhat smaller heat capacity, because in these last the pressure of the oxygen was only 20 atmospheres instead of 35 atmospheres. This change involves a further loss of water equivalent of 1.1 grams, or about 0.03 per cent. In the final column given below all the results are reduced to the same standard by adding 0.0003° to the figures in the last column obtained from Experiments 6 and 7 for 1 gram of sugar.

These two experiments just mentioned were made before the experiments with liquids, while Experiments 8 to 11 were made at the very conclusion of the whole research. The essential identity of the two sets is pleasing. Because of the close agreement of the results, the final figures in the last column are given to the fourth decimal place.

COMBUSTION OF SUGAR.

Final Series.

No. Exp.	Thermometer.	Weight of sugar.	Obs. rise of temperature.	Corr. for stirring and iron burnt.	Corr. for HNO_3.	Corr. temp. change	Temp. change for 1 gram sugar.	Temp. change for 1 g sugar corr. to lowest heat capacity.
6	B	1.5703	1.669°	—0.013°	—0.002°	1.654°	1.0533°	1.0536°
7	B	2.1784	2.312	—0.015	—0.002	2.295	1.0535	1.0538
8	B	2.0045	2.132	—0.016	—0.003	2.113	1.0541	1.0541
9	B	2.0563	2.187	—0.017	—0.002	2.168	1.0543	1.0543
10	B	2.0780	2.310	—0.017	—0.002	2.291	1.0539	1.0539
11	J	1.8772	1.997	—0.016	—0.003	1.978	1.0537	1.0537
								1.0539

Thus with the new heat capacity (0.32 per cent. less than in the previous series) the rise of temperature caused by 1 gram of sugar is 1.0539°, the extremes being less than 0.04 per cent. divergent from this mean. The preliminary series recalculated over to the basis of the new heat capacity would give 1.0545°, a value slightly greater, but probably within the limit of error of the first crude set of experiments where the individual determinations varied somewhat widely. It seems probable that the value 1.0539° is a correct one, and it may be used in subsequent work as the basis of conclusions concerning the relative heats of combustion with other substances as compared with sugar.

The Heat of Combustion of Benzene.

Two of the samples prepared for the previous work were still available.[1] These samples had been purified by several careful crystallizations: Sample A was from Merck's best grade of benzene and Sample B from Kahlbaum's "thiophenfrei" material. These had been preserved in well protected glass bottles with good ground-glass stoppers. Nevertheless, because they had been standing in this way for over two years it was thought best to prepare another specimen. Accordingly a new sample (C) was purified from Kahlbaum's "thiophenfrei" benzene by four successive crystallizations. In each case only about a third of the liquid was allowed to solidify. The crystals were allowed to drain slowly so that adhering mother liquor should be washed off by the liquid formed through the melting of the crystals themselves. In a determination conducted with all the ordinary precautions, no difference could be detected between the freezing point of the fourth crop of crystals and that of the mother liquor from which they had been crystallized. Furthermore, the temperature remained constant until practically all the liquid was frozen.

---

[1] *Proc. Am. Acad.*, 42, 578 (1907); *Z. physik. Chem.*, 59, 538 (1907).

It has been mentioned at the first of the paper that the earlier method of combustion was finally modified, and that a more trustworthy arrangement was made. Before describing the modifications it is worth while to record the results of new experiments with the use of the earlier method.

In brief, this old method was as follows: The benzene was sealed and weighed in a completely filled glass bulb with very thin walls. The bulb was placed in the platinum crucible within the bomb, on the top of a small weighed quantity of sugar, which was ignited as usual by the coil of iron wire. The burning of the sugar burst the bulb and inflamed the benzene. The remainder of the manipulation was precisely as described above in the case of cane sugar. The heat capacity was the same as that used in the earlier experiments, Nos. 1 to 5, with cane sugar, and the rate of stirring was the same. The following table contains the results of the combustion of benzene in this way, the larger crucible with a diameter at the top of about 35 centimeters having been used as the capsule for the combustion, and the oxygen containing about 5 per cent. of nitrogen.

COMBUSTION OF BENZENE.

Preliminary Series with Large Crucible.

No. of Exp.	Thermom.	Weight of benzene in vacuum. Gram.	Weight of sugar. Gram.	Correction for sugar burned.	Rise due to benzene	Rise per gram benzene.
12	B	0.7108	0.2715	0.286°	1.887°	2.655°
13	B	0.7535	0.2359	0.248	2.003	2.658+
14	B	0.6049	0.2711	0.285	1.607	2.657+
					Average,	2.657°

Thus 1 gram of benzene is shown to raise the calorimetric system 2.657°. Richards, Henderson and Frevert found for the combustion of benzene with oxygen containing the same amount of nitrogen the value 2.655°.[1] The difference of 0.002° is not much beyond the limit of error of the average and is just what one would have expected as a result of better mixing of the liquid in the calorimeter. Thus if the ratio of benzene to sugar 2.657/1.051 = 2.528, found by the new investigation, is compared with the older ratio 2.655/1.0504 = 2.528 (or, if the weights of benzene and sugar are both corrected to the vacuum standard, 2.526), the essential identity of the results is seen to indicate that the experimentation was really identical and to verify the previous work as far as accidental errors are concerned. The error due to the inadequate stirring in the older work was a constant one, and affected the experiments with sugar and with benzene in like manner, hence it is essentially eliminated from the ratio.

---

[1] *Proc. Amer. Acad.*, 42, 588 (1907).

It will be remembered, however, that the earlier experimenters found a higher result when the oxygen contained less nitrogen, showing that combustion with 5 per cent. of inert gas present had not been complete; and they were inclined to believe that even the highest value which they obtained, about 0.3 per cent. higher than the one just given, was not quite high enough. Pure oxygen was at that time not obtainable under this pressure, and the cause of the incomplete combustion was pointed out as a matter well worth further investigation. An important point in explaining the anomaly is the following fact demonstrated by repeated experience, namely that whenever the benzene vapor had a chance to become intimately mixed with the gases in the bomb before combustion took place (as for example, by the premature bursting of the glass bulb by the pressure of the oxygen), the combustion was always incomplete. Under these circumstances we have detected the odor sometimes of nitrobenzene and sometimes of phenol—substances which are notoriously hard to burn. Once after rinsing out the bomb and diluting the liquid as usual with sodium hydroxide, the solution turned yellow immediately before the color change in the phenolphthalein took place—a phenomenon which might have been due to the presence of paradinitrobenzene.

These observations clearly point to the inadequacy of the usual method of burning a volatile liquid absorbed in a mass of cellulose, because under these conditions some of the liquid inevitably evaporates prematurely. They also form an important step, as has been said, in the train of reasoning which guided us to a better result.

In the present work we have been fortunate enough to solve the difficulty and discover the cause of the incomplete combustion of the benzene as well as to show why this cause does not affect experiments with non-volatile substances, like sugar. We will show also that the suspicion that the true value is yet higher than the highest value found before was correct. The answer to the riddle was found only after protracted investigation. In the search for further light and experience, other liquids, especially methyl butyrate, methyl isobutyrate, and ethyl propionate, were subjected to calorimetric combustion, and it was through experience gained in working with these less combustible compounds that the error in the results of previous investigators with all volatile liquids became manifest. Therefore it may not be out of place here to describe the various methods which were tried in the attempt to obtain complete combustion of the esters.

At first the earlier method just described was used. This method was, however, obviously inadequate, for after the bomb was opened a distinct odor of the ester, varying in intensity in different experiments but always recognizable, could be detected in the issuing gases. Moreover, in several cases there was a deposit of carbon in the crucible. It seemed possible that the carbon was formed from sugar protected from the oxygen by the molten glass of the bulb, hence in a few experiments the bulb was placed on a small staging of heavy platinum above the surface of the sugar. In this way the sugar should have a chance to become thoroughly ignited before the melted glass could fall upon it. The plan succeeded, indeed, in eliminating the carbon, but the odor of ester was still very distinct. Evidently, at the moment when the bulb burst, some of the vapor was projected upward at a rate greater than the rate of propagation of the explosion; and as the amount which thus escaped was evidently insufficient to form an explosive mixture throughout the bomb, it escaped combustion.

The amount left unburned would naturally be greater, the greater the concentration of nitrogen present, for the effect of an inert gas in retarding the rate of propagation of an explosive wave is well known.[1] It is conceivable that the retarding effect here was so great that some of the vapor escaped combustion entirely. Dixon[2] has shown that in some cases an excess of one of the reacting gases also has a retarding effect, but this cause of incomplete combustion does not seem to have affected our work, probably because in no case the pressure of the oxygen exceeded 35 atmospheres.

These considerations adequately explained the effect of increasing the concentration of the nitrogen, and furnished the leading idea in effecting improvement.

The following arrangement was then tried. The bottom of the platinum crucible was so distorted as to form on one side a depression large enough to hold the bulb. On the bottom of the crucible, now somewhat above the bulb, sugar was piled in such a way that the capillary was buried in it. It was hoped that, when the bulb burst, the liquid would be projected into the burning sugar. Also, since the sugar was on a higher level, the vapor rising upward would have to pass through an area filled with flame. But here too there was evidence that part of the vapor escaped combustion.

---

[1] See Mellor, "Chemical Statics and Dynamics," pp. 466ff.

[2] *Phil. Trans.*, 184, 97 (1893). *J. Chem. Soc.*, 69, 774 (1896); 75, 631 (1899).

After a few fruitless experiments with an entirely different method, whereby it was hoped to reduce the rate of vaporization of the ester and thus to obtain a slower combustion, the use of the thin-walled bulbs was again resorted to The bulb was now placed in the bottom of a much narrower crucible. About half way up in this crucible and on top of the bulb was fixed a rectangular plate of thin perforated platinum foil, and sugar was put on top of this. By having this plate rectangular instead of disc-shaped, there was room for the passage of the vapor around the sides of the plate and at the same time there was plenty of oxygen for the combustion. In this way the sugar was ignited first, and when the bulb burst the vapor was forced to pass up through the top half of the crucible, which was completely filled with flame. Thus complete combustion was obtained, so that no odor of ester could be noticed in the residual gas, and there was no carbon deposit within the crucible or bomb, but with 35 atmospheres pressure the combustion took the form of an explosion of considerable violence, as the appearance of the crucible testified. In order to reduce the rate of combustion, the concentration of oxygen was therefore diminished; with 20 atmospheres of oxygen everything went smoothly, although the temperature within the crucible was still sufficient to fuse the thin platinum foil, especially where the iron oxide came in contact with it. Afterwards platforms of ignited asbestos paper were substituted for the platinum With the thick asbestos paper there was some tendency toward carbonization in the bottom of the crucible, but with thinner paper this tendency disappeared. The thin asbestos fused together into a globule with the iron oxide—perhaps forming an iron silicate. That this gave rise to no thermal effect was proved by a combustion of sugar alone in which a similar asbestos platform was used. The agreement of this determination with the previous ones also proved the absence of any carbonaceous matter in the asbestos which had escaped combustion in the lower temperature of the Bunsen flame. In this way seemingly complete combustions of the esters, which yielded concordant results, were finally obtained.[1]

Having thus mastered the technique of the combustion of volatile liquids, we returned to the work upon the hydrocarbons, which are far more easily burned than esters. It was not a great surprise to find that the new method yielded results which were higher than those previously found, for the earlier results had been thought too low. In order to make sure, however, that the increase was not due to the presence of combustible matter in the asbestos, very thin glass platforms (made from microscopical cover-glasses) were substituted for the shelf upon which the sugar was to be placed. To review, briefly, the method of combustion for benzene, in its final form, was as follows: the benzene in a very thin glass bulb was placed in the bottom of a narrow platinum crucible, 2 cm. in diameter and 2.5 cm. high. A few millimeters above the bulb was fixed a small platform of thin glass bearing a weighed quantity of powdered sugar. The passage of a current through the coil of iron wire ignited the sugar, which in its turn burst the bulb and ignited the benzene at a moment when the whole top of the narrow crucible was filled with flame from the burning sugar. Thus none of the benzene vapor could escape ignition. The trouble with the old method had been that the larger crucible was too wide. Moreover, the sugar had been beneath the benzene instead of above it, so that some of the benzene escaped unconsumed. The amount which thus escaped was greater when there was more nitrogen present than when there was less. Obviously, with non-volatile compounds like sugar the width of the crucible would make no difference.

---

[1] Although we were not entirely sure of the purity of the esters, they were probably as pure as most organic liquids which have been used by other physico-chemical investigators. Therefore we venture to give, for what they are worth, our results on methyl isobutyrate, which are typical This ester had proved harder to burn than the others mentioned above. Therefore when the method was perfected it was applied to this one first, in order to be sure that it was capable of dealing with the worst cases. In the determination given below no ester smell could be detected and there was no carbon in the bomb The ester supplied by Kahlbaum had been carefully

There follows a series of determinations carried out as described, with always the same quantity of water in the calorimeter.

In a few cases there was conclusive evidence to show that the glass bulb had been broken by pressure previous to the combustion. This

fractionated and dried with calcium chloride, and the fraction boiling between 91.4°–92.0° at 754 mm. was taken. No impurity was detected in this particular sample.

The combustions were made with 8.0 per cent. nitrogen in the bomb.

DATA FOR THE HEAT OF COMBUSTION OF METHYL ISOBUTYRATE.

Therm.	Wt. ester in vacuum.	Observed rise corrected.	Correction for sugar burned.	Correction for iron wire, stirring and HNO_3.	Corrected rise due to ester.	Rise per gram ester

J..........	0.6546	1.358	—0.152	—0.020	1.186	1.812
J..........	0.5147	1.134	—0.135	—0.017	0.932	1.811
J..........	0.6532	1.454	—0.255	—0.018	1.181	1.808
					Average,	1.810

Since a gram of sugar caused a rise of 1.0539° in the same system, methyl isobutyrate on burning is seen to evolve 1.717 times as much heat as an equal weight of sugar. Hence the molal heat of combustion in constant volume of methyl isobutyrate is 2901 kilojoules or 694.0 calories. Thomsen found for the vapor 717.6 calories under constant pressure.

Favre and Silbermann find for methyl butyrate (liquid) 693.4 cal. (*Annales chim. phys.*, [3] 34, 441 (1852).

Heat of vaporization 7.9 cal. (Schiff, *Liebig's Ann.*, 234, 338 (1886)).

was detected by means of the odor of the benzene in the small amount of oxygen always allowed to escape just before the combustion. Such experiments were of course rejected. Otherwise, all the experiments made are recorded in the following table:

HEAT OF COMBUSTION OF BENZENE.

Final Series.

Exp No.	Sample	Per cent N_2	Wt benzene in vacuum	Wt sugar	Change of thermometer corrected	Correction for sugar burned	Correction for iron wire and nitrogen burned and for stirring	Rise due to benzene.	Rise due to 1 gram benzene (weighed in vacuum)
15	B	8 0	0 7763	0 2376	2.347	—0 250	—0 019	2 078	2 677
16	B	8 0	1 0144	0 1050	2 847	— 0 111	0 021	2 715	2 676
17	B	8 0	0 6443	0.2431	1 999	—0 256	—0 019	1 724	2 676
18	B	2 6	0 7480	0.3199	2 355	—0 337	—0.017	2 001	2 675
19	C	2 6	0 7365	0 2522	2 252	-0 266	0 017	1 969	2 674
20	A	2 6	0 7360	0 2068	2 202	—0 218	-0 017	1 967	2 678
21	C	2 6	0 7618	0 2420	2 307	-0 255	- -0 017	2 035	2.672
22	A	2 0	0 6860	0 2823	2 152	-0 298	- 0 018	1 836	2 677
								Average =	2 6750°

Thus one gram of benzene weighed in vacuum evolves enough heat on combustion to raise the special calorimetric system employed 2 675°, the figure having a probable error of 0 0004. The extreme deviation from the mean amounts to less than 0 003°, which, although larger than in the case of sugar, is nevertheless as small as could be expected, considering the complication of the process and the fact that less than a gram of benzene was usually used in the combustion.

Not only is the series satisfactory as a whole, it is also convincing as regards the agreement in several samples of benzene. The average value for Sample B is 2 676°, for A 2 675°, and for C but slightly less, 2 673°. These differences are within the reasonable limit of error, especially since only two determinations of each were made with Samples A and C.

It is interesting to note that the presence of nitrogen has no longer any effect upon the completeness of combustion. Of the eight determinations in the table, the first three were made in the presence of 8 per cent. of nitrogen, whereas in the last five the per cent. of nitrogen was 2 6 or less. The amount of heat evolved in the first three, per gram of benzene, was 2 676, in the last five 2.674. This difference is not greater than the possible experimental error. It is in fact in a direction opposite from that which would have been expected if the difference had any significance. This is a very satisfactory evidence that the combustion was complete in every case, for if it had been incomplete with 2.6 per cent.

of nitrogen, it would have unquestionably been still less complete with 8 per cent.

The only effect of decreasing the nitrogen in our accepted experiments was to cause the correction of nitric acid formed to become noticeably smaller, so that in many instances where the nitrogen amounted to 2.6 per cent. or less, this correction amounted to practically nothing. The actual amounts of nitric acid found were as follows: with 8 per cent. of nitrogen, 0.04, 0.06, 0.03 gram, respectively; with 2.6 per cent. of nitrogen in only two experiments (the second and last) did the amount of nitric acid exceed 0.01 gram.

Circumstantial evidence supported this conclusion that complete combustion of the benzene had at last been obtained. No indications of incompleteness—neither deposited carbon nor residual odor—were perceptible in the bomb after combustion. No test was made for carbon monoxide, because Richards, Henderson and Frevert were unable to find any traces of this gas even with their less efficient method.

In order to show that the first rush of benzene vapor upon the bursting of the bulb in the moment of ignition had not so blown about the powdered sugar that part of it escaped combustion, the following test was made in one case (No. 21). After the combustion the bomb had been rinsed out with very pure water and the nitric acid titrated with sodium hydroxide solution, the sodium nitrate solution was evaporated to dryness in a tared platinum dish. The gain in weight of this dish amounted to 0.0008 gram more than the amount of sodium nitrate calculated from the quantity of sodium hydroxide solution used. Tests by the resorcinol method and with Fehling's solution (after treatment which would have inverted sugar) failed to show any traces of sugar. Even if the gain was really unburned sugar, the temperature rise due to it would have been only 0.0008°, which is beyond the limit of error of the thermometric readings.

Another experiment (No. 22), in which the sugar was compressed into pellets so that it could not be easily blown about, gave a result in perfect agreement with the rest of the series. Benedict and Fletcher[1] have shown that the only important effect of this treatment is a diminution of the speed of reaction.

After one experiment a light deposit of a brownish red powder was found on the walls of the bomb. This proved, upon examination, to be an oxide of iron, obviously without effect upon the value derived from the determination, because the heat of combustion of the iron was always allowed for.

After scores of combustions, the crucibles showed no visible signs of having combined with carbon. The high temperature and the presence of an excess of oxygen undoubtedly prevented this cause of error.

---

[1] This Journal, 29, 753 (1907).

The heat capacity of our calorimetric system has not yet been determined by the method of summing up the water equivalent of the component parts.[1] Thus the results in this paper are to be expressed as ratios, the standard being the temperature rise produced in our calorimetric system by one gram of sugar.

Expressed in this way, our final results are as follows:

Average rise produced in the calorimetric system by one gram of benzene	2.6750°
Average rise produced in the calorimetric system by one gram of sugar	1.0539°
Ratio benzene to sugar = 2.6750/1.0539	2.5382

This is now directly comparable to the results of Richards, Henderson and Frevert. Their ratio of the heats of combustion of like weights of benzene and sugar (when the oxygen was as pure as they could make it) was 2.534. If vacuum corrections for the weights of sugar and of benzene are applied, their value falls to 2.532. Our heat of combustion is thus about 0.26 per cent. higher. This difference was only to be expected, since these investigators clearly showed that their figure was probably less than the true one, on account of the effect of the nitrogen present under the conditions of the earlier experiments. Although the lowering of the heat of combustion was not exactly proportional to the per cent. of nitrogen present, one would have inferred by extrapolation from their experiments that the true value must be about 2.54, in close agreement with our new value 2.538.

Stohmann's ratio for the heat produced by benzene in comparison with that by sugar is 2.5225.[2] This ratio is based upon the determinations for benzene done with the Berthelot bomb. Stohmann also made some earlier determinations with the apparatus of Berthelot and Vieille (a modification of that of Favre and Silbermann), in which the benzene was burned from a lamp in a stream of oxygen. The average of these determinations gave the value 9.977 Calories per gram of liquid benzene at 17°. The ratio derived from this is 2.5275. Thus the results of Stohmann's two series are a little over 0.6 per cent. and 0.4 per cent., respectively, lower than our ratio. Berthelot's[1] ratio is lower still, about 2.520. Julius Thomsen[2] burned benzene vapor, finding a result to which Stohmann applied corrections for the heat of vaporization, using Regnault's formula for the heat of vaporization, and Kopp's value for the molecular heat capacity of liquid benzene. Thomsen's value thus reduced to the heat of combustion in constant volume of liquid benzene at 17° is for a gram of benzene, 10.135 Calories, a value much higher than the others.

---

[1] Richards and Rowe have recently devised a new method for determining specific heats (*Proc. Am. Acad.*, 43, 473 (1908)) and are further perfecting it. It seems probable that with slight modifications their method can be used for the accurate determination of the heat capacity of a bomb. This method is more easily carried out in a chemical laboratory than is the electrical method of Jaeger and von Steinwehr (*Verhandl. d. d. physik. Ges.*, 5, 50 (1903); *Ibid.*, 5, 353 (1903); *Z. physik. Chem.*, 53, 153 (1905))

[2] Stohmann and Langbein, *J. prakt. Chem.*, 45, 313 (1892); 40, 77, 81 (1889); Stohmann, Rodatz and Herzberg, *Ibid.*, 33, 241 (1886).

The most probable figure for sugar is that of Fischer and Wrede,[3] who found that a gram of sugar on complete combustion yields 16.545 kilojoules of heat energy. If we accept this value, a gram of benzene is found from our work to yield 2.5382 × 16 545 kilojoules = 41.99 kilojoules. If a kilojoule at 19° is taken as 4.179 Calories, the heat of combustion of a gram of benzene is 10.049 Calories, a result almost as high as Thomsen's.

In the more usual and more generally useful standard, 1 mole or gram-molecule of benzene (78.05 grams) evolves 3278 kilojoules. or 784.3 Calories on combustion.

Heats of Combustion of the Octanes.

The next substances whose heats of combustion were studied were five isomeric octanes. These compounds were furnished us by Dr. Latham Clarke, of this laboratory, who is now engaged in an attempt to prepare all the possible isomeric octanes. The octanes burned were:

Normal octane,[4]—$CH_3CH_2CH_2CH_2CH_2CH_2CH_2CH_3$, boiling point 124.5°.

2-Methyl heptane or iso-octane,[5]  $CH_3\underset{\displaystyle CH_3}{\underset{|}{C}}HCH_2CH_2CH_2CH_2CH_3$, boiling point 116.0°.

2,5-Dimethyl hexane or diisobutyl,[6]  $CH_3\underset{\displaystyle CH_3}{\underset{|}{C}}HCH_2CH_2\underset{\displaystyle CH_3}{\underset{|}{C}}HCH_3$, boiling point 108.4°.

3,4-Dimethyl hexane or di-secondary butyl,[7]  $CH_3CH_2\underset{\displaystyle CH_3}{\underset{|}{C}}H\ \underset{\displaystyle CH_3}{\underset{\diagdown}{C}}HCH_2CH_3$, boiling point 116.2°.

3-Ethyl hexane,[1] $CH_3CH_2\underset{CH_2CH_3}{\underset{|}{C}}HCH_2CH_2CH_3$, boiling point 115°.

Great care was taken by Dr. Clarke in the preparation of these compounds and they were undoubtedly purer than most organic liquids of this sort. The earlier preparations formed a small amount of black precipitate on standing over mercury, but the final specimens used in the combustion experiments were practically free from unknown contamination which caused this effect. Careful experimentation showed them to be free from sulphur and halogen, and they were dried by distillation over sodium.

Two samples of 2,5-dimethyl hexane, which had been prepared by different methods, were used. One sample had been prepared by the action of sodium on isobutyl iodide, $(CH_3)_2CHCH_2I$. The other had been prepared by treating acetoacetic ester with sodium and isobutyl iodide. By the action of a magnesium alkyl iodide, the ketone, resulting from saponification of the product obtained above, was reduced to the hydrocarbon. The first sample boiled 0.2° lower than the second and there were also differences of a few units in the fourth decimal place of the densities and in the fifth decimal of the refractive indices, but no differences in the heats of combustion could be detected. In the table, these samples have been marked A (b. p. = 108.3–108.5°) and B (b. p. = 108.1–108.3°). Dr. Clarke considers Sample A slightly purer.

The method of burning the octanes was essentially the same as that used for benzene, except for a slightly different arrangement of the sugar used to start the ignition. In the present case this substance was compressed into pellets, one of which was placed upon the glass plate above the bulb and another, much smaller, was fixed in the coil of iron wire suspended about a millimeter above the large pellet. Another minor modification made in the case of the latter experiments was the invariable use of flattened bulbs instead of spherical ones sometimes employed for holding the liquid. This was especially important because of the considerable compressibility of the octanes; for flattened bulbs are much more flexible than spherical ones, and the danger of their breaking when the bomb is charged with gas is much less.

With the octanes, as with benzene, whenever the bulb broke previous to the combustion, the burning was never complete. Each of these octanes has a characteristic odor and the presence or absence of any smell in the gases after combustion formed a very delicate test of the completeness of the combustion. Whenever the bulb did not break prematurely, the combustion was always complete.

The effect of the amount of nitrogen present in the bomb was tested in the case of one octane (diisobutyl). Since combustions in which the concentration of the nitrogen exceeded 6 per cent. gave results identical with those with only 2 per cent., it was not thought necessary in the other cases to evacuate the bomb before running in the oxygen. The table following gives the rise per gram of octane in the same calorimetric system as that used in the final experiments with benzene. For the last three compounds given in the table the newer form of jacketing apparatus was used. The somewhat increased air space around the calorimeter can involve the heating of more air, but this amount in a system whose heat capacity is nearly 3800 calories is entirely negligible.

---

[1] This substance has not been described in full by Dr. Clarke.

Data Concerning Heat of Combustion of Octanes.

---

[1] Experiment 28 is 0.6 per cent. higher than the values for the other experiments, an amount very much greater than can be explained by ordinary experimental error. It is included in the table, because no fault was found in it adequate to account for this discrepancy. The error was probably caused by a mistake in reading one of the thermometers. A single division of the scale (the hundredth of a degree) would have caused the error in question, and every one knows how easy it is to make such a mistake as this. Because of the consistent verdict of the other five experiments, we have not included the result of Experiment 28 in the average. Those who wish to retain it will use 3.040° as the average rise caused by a gram of diisobutyl instead of 3.037°, as given above.

No completed determinations are omitted from the table; all are given which were actually carried out, except those in which the bulb was known to have burst prematurely.

Thus the rises of temperature in our calorimetric system caused by the combustion of the five octanes, namely, the isomeric compounds, normal octane, diisobutyl, 2-methyl heptane, 3,4-dimethyl hexane, and 3-ethyl hexane, were found to be respectively, per gram of liquid, 3.041, 3.037, 3.044, 3.038, and 3.035. The differences are small, but seem to be really significant, because they are distinctly greater than the variations among the individual experiments on any one substance.

In order to express these results in terms of gram-molecules, it is necessary to compare these rises of temperature with those produced by a gram of sugar in order to transform the values into terms of energy. The following table contains these comparisons and gives in the first column the name of the substance, in the second column the rise in our system per gram as given above, in the third column these numbers divided by 1.0539 (the rise of temperature caused by a gram of sugar in the same system), in the fourth column the numbers in the third column multiplied by 16.545, in the fifth column these numbers multiplied by the gram-molecular weight, giving the heat of combustion of 1 mole in kilo joules, and in the last column the same data expressed in terms of calories.

In calculating these results, the molecular weight of the several octanes is taken as 110.11 and the equivalent of one joule is taken as 0.2393 calorie, the value based upon the work of Callendar and Barnes for the 19° calorie, the range over which our experiments were carried out:

HEATS OF COMBUSTION OF FIVE ISOMERIC OCTANES.

(In constant volume, measured at 20°.)

	Rise per gram	Ratio octane to sugar	Heat from 1 gram of hydrocarbon (kilojoules).	Heat of combustion of 1 mole in kilojoules	Heat of combustion of 1 mole in calories
Normal octane . .	3.041°	2.885	47.73	5256	1257
2,5-Dimethyl hexane	3.037	2.882	47.68	5250	1256
2 Methyl heptane. .	3.044	2.888	47.78	5261	1258
3,4-Dimethyl hexane .	3.038	2.883	47.70	5252	1256
3-Ethyl hexane	3.035	2.880	47.65	5247	1255

The five octanes thus have similar heats of combustion, ranging from 5,247 to 5,261 kilojoules, or a range of about one-quarter of 1 per cent. Of the five measured, 3-ethyl hexane has the lowest heat of combustion and 2-methyl heptane the highest. As far as has been discovered by a search into the literature of the subject, no one else has ever determined the heats of combustion of these substances. The differences observed above may represent real differences between the respective energy contents of the five substances; but because only small quantities were available for individual experiments on account of lack of material, the uncertainties of the averages are greater than in the case of benzene. This is especially true with regard to 3-ethyl hexane, of which only one determination was made. Nevertheless it is clear that these isomers are very near together in their heats of combustion, the deviation from the mean value, 5,253 kilojoules, being less than 10 kilojoules on each side, or less than 0.15 per cent. The significance of the figures will be considered later in the summary of all the results.

The Heat of Combustion of the Xylenes.

The only determinations of the heats of combustion of xylenes that have been made before this research was begun were those of Stohmann.[1] He was far from satisfied with the purity of his material, some of which he prepared himself, while part was obtained from the most reliable commercial sources. He neglected in his paper to give boiling points or any other data which might indicate the degree of purity. The combustions themselves were probably more reliable than those of the more volatile hydrocarbons, because of the higher boiling point and less evaporation before combustion, but evidently the figures need thorough revision.

The preparation of pure xylene is by no means an easy matter, as is so often the case with organic compounds. The original material used for the following determinations was the best that Kahlbaum could furnish. The samples had been many times carefully fractionated by electrical distillation in the course of the previous work.[2] Just before being used in the present work the specimens were dried over anhydrous copper sulphate and again distilled. The boiling points, corrected for the projecting thread of the thermometer, were found to be in excellent accord with those found in previous investigations. The following table records these boiling points with the pressures in parentheses, as well as the boiling points given by Schiff[3] and Perkin.[4] Schiff's readings, like ours, were corrected for the protruding column. In Perkin's the thermometer was wholly immersed in the vapor.

BOILING POINTS OF XYLENE.

	Richards and Jesse.	Schiff.	Perkins.
Orthoxylene.......	143.9°–144.2° (763)	141.1° (756.2)	142.6° (760)
Metaxylene........	138.8°–139.2° (761)	139.2° (759.2)	139.3° (760)
Paraxylene........	137.8°–138.1° (754)	138.1° (761.2)	137.5° (760)

About the boiling piont of orthoxylene there seems to be some doubt, the values ranging from 141° to 144°. Neither Schiff's nor Perkin's values agree very well with the present experience, but Woringer[1] has found 143.7°, a value not far from ours.

These substances were burned in the calorimetric bomb under exactly the same conditions as those used in the case of the octanes. Two of the determinations were vitiated by the premature bursting of the bulb containing the liquid. The experiment was nevertheless continued, to see what would happen, and in these cases a noticeable odor, resembling that of bitter almonds, could be detected afterwards. These, of course, were rejected. In all of the cases excepting the first combustion of paraxylene, the amount of nitrogen present in the oxygen was only two per cent. In this single case it was 6 per cent., but this difference caused no diminution in the heat of combustion. Therefore it is safe to assume that in all the cases the combustion was complete, especially as no odor or sign of deposited carbon was visible in any case. Only in two cases, the first combustion with metaxylene and the first combustion with paraxylene, was enough nitric acid formed to cause 0.001° change in the temperature. In these two cases this correction has been added to the correction for the iron wire burned. The stirring correction was in each case 0.002°, this also has been included with the other. The thermometer numbered B was used in all these determinations:

TABLE—DATA FOR HEAT OF COMBUSTION OF XYLENES.

No. of expt.	Substance.	Wt. xylene vacuum.	Wt. sugar.	Total corr. rise of temperature.	Corr for sugar.	Corr. for wire for stirring and for HNO_3 found.	Rise due to xylene.	Rise per gram xylene.
36	Orthoxylene....	0.6365	0.2421	2.018	—0.255	—0.017	1.746	2.743
37		0.7429	0.3276	2.402	—0.345	—0.016	2.041	2.747
38		0.7307	0.2528	2.288	—0.266	—0.016	2.006	2.745
							Average,	2.745
39	Metaxylene....	0.6871	0.2534	2.171	—0.267	—0.018	1.886	2.745
40		0.7019	0.2008	2.156	—0.212	—0.016	1.928	2.747
41		0.6828	0.3314	2.238	0.349	0.016	1.875	2.743
							Average,	2.745
42	Paraxylene.....	0.5955	0.3190	1 985	—0.336	—0.018	1.631	2.739
43		0.6980	0.2786	2.220	—0.294	—0 016	1.910	2.736
44		0.7380	0.2924	2.342	—0.308	—0.017	2.017	2.733
45		0.5871	0.2260	1.859	—0.238	—0.016	1.605	2.734
							Average,	2.736°

Thus a gram of orthoxylene on burning caused a change of temperature in our calorimetric system of 2.745°; and metaxylene gave precisely the same quantity, within the range of error of our experiments. On the other hand, paraxylene evolved slightly less heat, the temperature in this case rising only 2.736°.

---

[1] *Z. physik. Chem.*, 34, 264 (1900).

There follows a table which translates these temperature changes into terms of energy, similar to the table already given for the five isomeric octanes. In this case, as in the other, the change in temperature produced by a gram of sugar is taken at 1.0539 in our system: the energy represented by the combustion of 1 gram of sugar as 16 545 kilojoules, the large calories as equal to 4 179 kilojoules. The molecular weight of xylene is taken as 106.023.

HEAT OF COMBUSTION OF THREE ISOMERIC XYLENES.

(In constant volume, measured at 20°.)

	Rise of temp per gram.	Ratio of xylene to sugar.	Heat from 1 gram of hydrocarbon, kilojoules.	Heat of combustion of 1 mole in kilojoules.	Heat of combustion of 1 mole in calories
Orthoxylene .. .	2 745°	2 605	43 100	4570 0	1093.5
Metaxylene..... .	2.745°	2.605	43.100	4570.0	1093 5
Paraxylene....	2.736°	2 596	42 951	4554 0	1089.8

The orthoxylene and metaxylene give the same molecular heat of combustion, namely, 4570 kilojoules, or 1093.5 large calories, while the heat of combustion of the para compound is 0.35 per cent. less. Stohmann found for all three values (reduced to the same standard as those employed above) 1084 large calories, or nearly 0 9 per cent. lower than our value for the ortho- and metaxylenes and more than 0.5 per cent. lower than the new value for the paraxylene. This figure is not surprising. Stohmann, as has been said, was much dissatisfied with his determinations, so much indeed that he left the individual experiments unpublished, contenting himself with giving the averages. His hypothetical method of calculating the value from benzene, phenols, etc., need not receive serious consideration, although they yield results not far from ours. A careful survey of the literature seems to leave no doubt that the values given in the above table are by far the most probable of any thus far published.

Theoretical Considerations.

It is interesting now to bring into a single table the several results for the heats of combustion of the various compounds studied in this paper with the idea of comparing them and interpreting their variations. Together with the heats of formation of the several compounds expressed in kilojoules there are given below the boiling points of the various compounds and the approximate latent heats of vaporization. For the xylenes these values have been determined by Richards and Mathews in an investigation soon to be published; but for all but one of the octanes no data are available, and it was necessary accordingly to compute these latent heats according to the rule of Trouton. There are given also in the last column of the table several approximate heats of combustion of the substances in a vaporized condition—simply the sum of the quantities in the two preceding columns:

HEATS OF COMBUSTION OF LIQUID AND OF VAPORIZED HYDROCARBONS.
(In constant volume, determined at 20°)

	Boiling points	Heats of combustion of liquids (kilojoules).	Approximate heats of vaporization.	Approximate heats of combustion of vapors (kilojoules)
Benzene	80.4°	3277	30.8[1]	3308
Orthoxylene........	144.1	4570	37.5[1]	4607
Metaxylene..............	139.0	4570	36.1[1]	4606
Paraxylene...............	138.0	4554	35.6[1]	4590
Normal octane............	124.5	5256	33.8[2]	5290
2,5-Dimethyl hexane.....	108.4	5250	32.0±	5282
2-Methyl heptane........	116.0	5261	33.0±	5294
3,4-Dimethyl hexane ...	116.2	5252	33.0±	5285
3-Ethylhexane............	115.0	5247	33.0±	5280

This table presents several interesting relations, the most important of which may be here briefly summarized:

On comparing the heat of combustion of the liquid benzene, 3277, and the average heat of combustion of the liquid xylenes, 4565, it is evident that the addition of CH_2 causes an increase in the heat of combustion of 644 kilojoules. This is not far from the number found by Thomsen, namely, 671.[3] It probably, more nearly than Thomsen's value, represents the average effect of the addition of CH_2 in a homologous series, because in each of his experiments the liquids with higher boiling points were increasingly in error because of the increasing heat from his "Universal Burner." Accordingly in his work the differences must have been too large. It is evident, nevertheless, that the position of the CH_2 makes an important difference in the result; probably the same value is not to be expected from an aromatic series as from an aliphatic series, and the values are entirely different when oxygen is present.

In spite of these qualifications, the conclusion that the following thermochemical reaction,

$$-\overset{|}{C}H_2 + O_2 = CO_2 + H_2O + 644\text{ kj.},$$

holds true, at any rate in the case of aromatic substances when burnt in constant volume, is the least uncertain of all the theoretical inferences which may be drawn from the present work.

---

[1] Observations by Richards and Mathews, as yet unpublished.

[2] Longuinine, *Compt. rend.*, 121, 557 (1895). The value computed independently by Trouton's rule for the heat of vaporization of normal octane was 34 instead of the value 33.8 found by Longuinine. This close agreement increases one's confidence in the other values calculated in the same way.

[3] This value is found from Thomsen's results from the aromatic hydrocarbons (*Thermochem. Untersuch.*, 4, 221) by subtracting from the average difference (161.8 Calories) corresponding to CH_2 the values 0.6 Calorie for correcting to constant volume, and 0.7 Calorie to allow for the difference of latent heat of evaporation caused by adding CH_2.

Because the heats of combustion of octanes on the average exceed those of the xylenes by 688 kilojoules, one might infer that each gram-atom of hydrogen in combination with carbon caused an increasing heat of combustion of 172 kilojoules. The addition of four hydrogens to each molecule of xylene to make an octane is nevertheless associated with important changes in the relations of the carbon atoms to one another, and these changes may be of considerable thermochemical effect. Hence it is not safe to conclude that a single gram-atom of hydrogen, even when united with carbon, will always increase the heat of combustion by 172 kilojoules, and the futher inference that because CH_2 adds 644 and H_2 adds 344 a single carbon would cause 300 kilojoules additional heat is likewise uncertain.[1]

Enough evidence has been collected to suggest the possibility of finding yet other interesting and fundamental relations and to make the collection of many more figures of the highest accuracy desirable. It will be necessary to investigate with the utmost precision a great number of typical cases of all kinds, in order to be sure of any generalization. In the fulfilment of this program, it is hoped that further careful work of this kind may be undertaken at Harvard University in the immediate future.

In conclusion it is a pleasure to express our indebtedness to the Carnegie Institution of Washington for generous pecuniary assistance in the prosecution of this work.

Summary.

In further prosecution of the revision of thermochemical data, the heats of combustion of benzene and a number of octanes and xylenes were determined with unusual care. The object in choosing these substances was to endeavor to trace the effect of constitution or arrangement upon the heats of formation of isomeric substances and thus to obtain a more definite idea of the relation of total energy change to structure. Octanes in particular were chosen because the molecule is large enough to admit of considerable variety in the isomeric compounds, but not so large as to confuse the relationships. Simplicity in interpretation is also gained by having only two elements present. The hydrocarbons were prepared in a state of great purity by Dr. Latham Clarke, according to methods worked out several years ago for this purpose. In the execution of this work the adiabatic method of calorimetry was used with great success and in general the precautions used in previous work of this kind were adopted throughout, with several new improvements. The volatile liquids were sealed in flexible flattened glass bulbs and ignited by means of small weighed quantities of sugar placed above the bulb on a glass shelf, the substances both being contained in a very small narrow platinum crucible. When conducted in this way, the combustion was in every case complete; with a wider crucible the combus-

---

[1] See W. A. Noyes, "Organic Chemistry," pp. 44, 80, 85, 90, and 162.

tion was not always complete. The final results showed very satisfactory agreement among themselves.

In this way it was found that the heats of combustion of the following substances possess relative magnitudes, indicated by the numbers following the respective names: sugar, 1 0000; benzene, 2 5382; orthoxylene, 2 605; metaxylene, 2 605; paraxylene, 2 596; normal octane, 2 885; diisobutyl, 2 882; 2 methyl heptane, 2 888; 3,4 dimethyl hexane, 2.883; 3-ethyl hexane, 2 880 If the heat of combustion of sugar is taken with Fischer and Wrede as 16 545 kilojoules per gram and O = 16 000 is taken as the standard of molecular weight, the molal heats of combustion of the nine liquid hydrocarbons (in kilojoules, determined in constant volume at 20°) are as follows, respectively: benzene, 3,278; orthoxylene, 4570; metaxylene, 4570; paraxylene, 4554; normal octane, 5256; diisobutyl, 5250; 2-methyl heptane, 5261; 3,4-dimethyl hexane, 5252; 2-ethyl hexane, 5247 kilojoules. The deviations from one another, shown by the simple isomers, are comparatively small. The addition of CH_2 in aromatic compounds is seen to cause an increase in this heat of combustion of 644 kilojoules, or 154 Calories.

The differences between the isomers are so small that an attempt at definite explanation of their causes would be premature. Much more work of the most precise nature is necessary to afford firm basis for theory. It is hoped that this investigation will be continued, and that in the near future further data of this kind will be obtained in the laboratory of Harvard College, where these researches were made.

A REVISION OF THE ATOMIC WEIGHT OF PHOSPHORUS.

FIRST PAPER.—THE ANALYSIS OF SILVER PHOSPHATE.

BY GREGORY PAUL BAXTER AND GRINNELL JONES.

Received January 14, 1910.

Although phosphorus is one of the best known and most important elements, present knowledge concerning its atomic weight is somewhat inadequate. The early determinations of this constant by Dulong,[1] Pelouze,[2] Berzelius,[3] and Jacquelain[4] are widely discrepant and have no particular significance. Those by Schrötter, Dumas, van der Platts, and Berthelot, on the other hand, all give values not far from 31.0, and this value has been selected by the International Committee on Atomic Weights. Although these investigations have already been critically

[4] *Compt. rend.*, 33, 693 (1851).

discussed by Clarke,[1] Brauner,[2] and others, a few of the more important sources of error are briefly pointed out here.

Schrötter,[3] the discoverer of red phosphorus, converted weighed quantities of this substance into phosphorus pentoxide by combustion in a stream of oxygen. As the mean of ten determinations which varied from 30.94–31.06, he obtained 31.03 for the atomic weight of phosphorus. The oxygen used was slightly moist, as Brauner has pointed out, since, although it was dried by phosphorus pentoxide, it was finally passed through a tube containing calcium chloride! The phosphorus pentoxide formed during the combustion must have retained this small amount of water, which would make the atomic weight of phosphorus appear too low. Schrotter admits that the combustion was incomplete, and since this error would tend to raise the atomic weight of phosphorus, he concludes that the true value is 31.00

Dumas[4] titrated the trichloride of phosphorus against silver after decomposing the trichloride with water. Since the sample used did not boil at a constant temperature but distilled between 76° and 78°, it must have been impure. If it contained oxychloride, as Clarke has suggested, the atomic weight of phosphorus would be found too high. Dumas overlooked the solubility of silver chloride and therefore used the wrong end-point in these titrations. Furthermore, no precautions are mentioned either for preventing access of water to the material before weighing or for preventing the reduction of the silver salt by the phosphorous acid formed in the decomposition of the trichloride with water. Recalculated on the basis of the atomic weight of silver as 107.88, his five analyses give results which vary between 30.99 and 31.08. The average is 31.03.

Van der Platts[5] made two determinations by each of three different methods. He obtained the values 30.90 and 30.97 by the precipitation of silver from silver sulphate solution with phosphorus. His results from the analysis of silver phosphate were 31.08 and 30.95. He gives no details of the method of preparing and analyzing this substance, merely making the statement: "It is difficult to be sure of the purity of this salt." Finally, by the combustion of yellow phosphorus in oxygen he obtained the results 30.99 and 30.96. The very meager descriptions of these experiments preclude criticism.

Using Leduc's data for the densities and compressibilities of phosphine and oxygen, Daniel Berthelot[6] has calculated, by the method of limiting densities, the molecular weight of phosphine to be 34.00 and the atomic weight of phosphorus to be 30.98.

Very recently Gazarian[1] has obtained a considerably lower value for the molecular weight of phosphine, 33.93. This value was calculated from the experimentally determined weight of the standard liter by the four methods of molecular volumes (Leduc), limiting densities (Berthelot), critical constants (Guye), and "indirect" limiting densities (Berthelot). The different methods give essentially identical results, except in the case of the direct method of limiting densities. By the latter method a value six-hundredths of a unit higher is obtained, but Gazarian rejects the result on the basis of inaccurate knowledge of the compressibility of phosphine. It is highly desirable to obtain more certain knowledge of the compressibility of phosphine, since the method of limiting densities is the most reliable of all the methods for applying the correction to the densities made necessary by deviations from the laws of a perfect gas.

The other methods are burdened with arbitrary assumptions and empirical constants, and furthermore Baumé[2] has shown that both the method of molecular volumes and the method of critical constants give correct results only with gases for which the ratio $\frac{T_c}{4P_c}$ is nearly 1, whereas for phosphine this ratio is 1.26.

If the molecular weight of phosphine be assumed to be 33.93, the atomic weight of phosphorus is 30.91. In the light of this low result it is unfortunate that Gazarian prepared phosphine by only one method, and that he did not determine the purity of the gas, *i. e.*, by absorption. Gazarian used the method of Matignon and Trannoy[3] which consists in heating calcium phosphate and aluminium together until they react, and then treating the product of this reaction without further purification with water in a gas generator. Matignon and Trannoy show that the gas prepared in this way by them contained about 3 per cent. of hydrogen, probably derived from calcium contained by the phosphide. In this case some calcium nitride would be formed, since the phosphide was made in air, and this would produce ammonia as an impurity in the phosphine. Although the gas was purified by fractional distillation, according to Gazarian's statements hydrogen is difficult to eliminate, and a proportion of only four-tenths of 1 per cent. would be sufficient to lower the atomic weight of phosphorus one-tenth of a unit. Ammonia would be even more difficult to remove, since its boiling point is only 50° higher than that of phosphine. The effect of a given percentage of impurity is, however, much less with ammonia than with hydrogen, although in the same direction.

[2] Baumé, *J. chim. phys.*, 6, 76 and 86 (1908).

[3] *Compt. rend.*, 148, 167 (1909).

From the preceding brief summary it is evident that the uncertainty in the atomic weight of phosphorus is as great as one-tenth of a unit, and that, as Brauner remarks at the conclusion of his review of the subject, "a revision of the atomic weight of phosphorus with modern means is urgently necessary."

The analysis of silver phosphate was selected as one of the most promising methods of attacking the problem, since the per cent. of silver can be determined exactly by a method which has been carefully studied, especially in this laboratory. The accuracy of the result will therefore depend primarily upon the success attained in preparing silver phosphate in a perfectly definite and pure state. The greater part of the following research was devoted to the solution of this problem, which van der Platts found so difficult.

The analysis of the halogen compounds of phosphorus offers certain difficulties, owing to the ease with which these substances are decomposed by water, and to the necessity for oxidizing the phosphorous acid resulting from the decomposition of the halogen compounds with water before the addition of silver nitrate. An investigation upon the tribromide of phosphorus is now in progress in this laboratory. Phosphonium compounds were found utterly unsuited for exact analysis on account of their instability.

Purification of Materials.

Water.—All the water used in this research was made from the laboratory supply of distilled water by distillation, first from an alkaline permanganate solution, and then, after the addition of a trace of sulphuric acid, through a block-tin condenser.

Ammonia.—The best commercial ammonia was distilled into the purest water.

Nitric Acid.—The best commercial concentrated acid was twice fractionally distilled through a platinum condenser, with the rejection of the first third of the distillate. Every sample was shown to be free from chloride by careful nephelometric tests.

Hydrochloric Acid.—The best commerical C. P. acid, diluted with an equal volume of water, was distilled through a platinum condenser.

Hydrobromic Acid.—This substance was prepared in conjunction with Mr. F. B. Coffin, who was engaged in a parallel research upon the atomic weight of arsenic.[1] Commercial bromine was converted into potassium bromide by addition to recrystallized potassium oxalate. In a concentrated solution of this bromide, in a distilling flask cooled with ice, bromine was dissolved, and distilled from the solution into a flask cooled with ice. A portion of the purified bromine was then converted into potassium bromide with pure potassium oxalate as before, and the remainder of the bromine was distilled from solution in this pure potassium bromide. The product obtained was thus twice distilled from a bromide, the bromide in the second distillation being essentially free from chlorine. This treatment has already been proved sufficient to free bromine from chlorine.[1]

---

[1] Baxter and Coffin, THIS JOURNAL, 31, 297 (1909).

Hydrobromic acid was synthesized from the pure bromine by bubbling hydrogen gas (made by the action of water on "hydrone") through the bromine warmed to 40-44° and passing the mixed gases over hot platinized asbestos in a glass tube. The apparatus was constructed wholly of glass. The hydrogen was cleansed by being passed through two wash-bottles containing dilute sulphuric acid, and through a tower filled with beads also moistened with dilute sulphuric acid. The hydrobromic acid gas was absorbed in pure water contained in a cooled flask. In order to remove iodine the solution of hydrobromic acid was diluted with water and twice boiled with a small quantity of free bromine. Then, a small quantity of recrystallized potassium permanganate was added to the hydrobromic acid solution, and the bromine set free was expelled by boiling. Finally the acid was distilled with the use of a quartz condenser, the first third being rejected. It was preserved in a bottle of Nonsol glass provided with a ground-glass stopper.

The purity of the hydrobromic acid was tested by a quantitative synthesis of silver bromide. The silver used, which was kindly furnished by Mr. G. S. Tilley, had been prepared with all the necessary precautions for work on the atomic weights of silver and iodine.[2] The procedure used by Baxter[1] for the synthesis of silver bromide from a weighed amount of silver was followed in detail. In this experiment 6.02386 grams of silver yielded 10.48627 grams of silver bromide; hence, silver bromide contains 57.4452 per cent. of silver, while Baxter found as the mean of 18 determinations 57.4453 per cent. The hydrobromic acid was evidently pure.

Silver Nitrate.—Crude silver nitrate was reduced with ammonium formate, made by passing ammonia gas into redistilled formic acid. The reduced silver was washed with the purest water, until the wash-waters no longer gave a test for ammonia with Nessler's reagent, and was fused on sugar charcoal. The buttons were then scrubbed with sea-sand and thoroughly cleansed with ammonia and nitric acid. They were then dissolved in redistilled nitric acid, in a platinum dish. After the silver nitrate solution had been evaporated on a steam bath until saturated, an equal volume of redistilled nitric acid was added and the solution was cooled. The precipitated silver nitrate was very completely drained in a centrifugal machine, provided with platinum Gooch crucibles to retain the salt.[1] A similar recrystallization followed. The final product was preserved in Jena glass vessels under a bell-jar.

---

[1] Baxter, This Journal, 28, 1322 (1906).

[2] Baxter and Tilley, *Ibid.*, 31, 201 (1909).

Disodium Phosphate.—One kilogram of Merck's best disodium phosphate was dissolved in hot water in a porcelain dish and hydrogen sulphide passed into the solution for several hours. After standing for twenty-four hours, the solution was again heated, saturated with hydrogen sulphide and filtered. The filtrate was slightly green, owing to the presence of iron. The solution was boiled to expel the hydrogen sulphide and a small amount of green precipitate filtered out. The filtrate was still distinctly green. The sodium phosphate was then crystallized fifteen times, five times in porcelain with centrifugal drainage of the crystals in a large porcelain centrifugal machine, ten times in platinum vessels with centrifugal drainage of the crystals in platinum Gooch crucibles. The green color concentrated in the first mother liquor.

When tested by means of the Marsh test, this material was found to contain only a mere trace of arsenic, which was estimated to be 0.01 mg. in 10 grams of the salt. This small amount could have no effect on the analytical results, especially since the percentage of silver in silver arsenate is nearly the same as in silver phosphate. By means of the nephelometer it was proved that this material contained no chloride or other substances which could be precipitated by silver nitrate in the presence of dilute nitric acid.

Sodium Ammonium Hydrogen Phosphate.—The best commercial microcosmic salt was recrystallized four times in platinum vessels. It was tested for arsenic by Marsh's method with negative results and gave no opalescence visible in the nephelometer when tested with silver nitrate and dilute nitric acid.

Preparation of Trisilver Phosphate.

Silver phosphate was prepared by mixing dilute solutions of silver nitrate with solutions of sodium and ammonium phosphates. Since it is not feasible to purify silver phosphate by recrystallization, the conditions of precipitation must be so chosen that a pure product will be obtained at once.

In order to avoid inclusion and occlusion of silver nitrate, sodium nitrate, sodium phosphate, or mono- or disilver phosphate, all of the solutions for precipitation were made about 0.03 *N*. All samples after precipitation were thoroughly washed and allowed to stand in water for at least twenty-four hours, in order to convert occluded acid phosphates into trisilver phosphate. Qualitative tests for nitrate with diphenylamine and for sodium by the spectroscope showed that all of the first three substances named could be completely washed out.

---

[1] Baxter, This Journal, 30, 286 (1908).

Joly[1] states that disilver phosphate is stable in the presence of phosphoric acid containing 40 per cent. (11.8 *N*) of phosphoric anhydride, but is transformed into trisilver phosphate if the acid contains 38 per cent. (11.0 *N*) or less phosphoric anhydride. Since all the solutions used for the preparation of silver phosphate were nearly neutral, it is evident that the precipitation of disilver phosphate as a distinct phase in equilibrium with the solution is not to be feared.

It is, however, not such a simple matter to prove the absence of *occluded* disilver hydrogen phosphate or monosilver hydrogen phosphate. Much light is thrown on this point in a recent paper by Abbott and Bray[2] upon the dissociation constants of the three hydrogens of phosphoric acid, which were found to be 1.1×10^{-2}, 1.95×10^{-7} and 3.6×10^{-13} respectively. Since phosphate ion ($PO_4^{\equiv}$) is almost completely hydrolyzed to monohydrophosphate ion ($HPO_4^{=}$), even in slightly alkaline solutions, and since in slightly acid solutions dihydrophosphate ion ($H_2PO_4^-$) acquires an appreciable concentration, the possibility of occlusion must be examined with special care.

The concentrations in the following table are either taken directly from a table given by Abbott and Bray or calculated from these numbers with the help of the values of the dissociation constants of phosphoric acid. The values are expressed in formular weights per liter, the total concentration of the salt being in each case 0.05.

	$NaNH_4HPO_4$.	$Na_2NH_4PO_4$.
$H_2PO_4^-$	0.001184[3]	0.000002[4]
$HPO_4^{=}$	0.03265[3]	0 03219[3]
$PO_4^{\equiv}$	0.0000016[4]	0.001123[3]
OH^-	0.00000079[3]	0.000502[3]
H^+	0.0000000075[4]	0 000000000012[4]

It will be noted that the replacement of the remaining hydrogen in sodium ammonium hydrogen phosphate by sodium decreases the concentration of the hydrogen ion to 0.16 per cent. of its value in the microcosmic salt solution and decreases the concentration of dihydrophosphate ion to 0.2 per cent. of its former value. The concentration of monohydrophosphate ion remains essentially unchanged, while the concentration of phosphate ion is increased seven hundred times. Disodium phosphate doubtless takes a position intermediate between the other two solutions

---

[1] *Compt. rend.*, 103, 1071 (1886).

[2] This Journal, 31, 755 (1909).

[3] These values are taken directly from the table of Abbott and Bray.

[4] These values are calculated from the others in the above table by the aid of the following equations:

$$(H^+)(OH^-) = 0.59 \times 10^{-14}$$

$$\frac{(H^+)(PO_4^{\equiv})}{(HPO_4^{=})} = 3.6 \times 10^{-13} \qquad \frac{(H^+)(HPO_4^{=})}{(H_2PO_4^-)} = 1.95 \times 10^{-7}$$

in this regard, since it is more alkaline than microcosmic salt and less so than disodium ammonium phosphate. The numbers given above refer to solutions which are five times as strong as those used in this research, but the conditions in the more dilute solutions must be very similar. Furthermore, the exact values have no great importance, as the concentrations of the various ions change continuously during precipitation. It is evident from the figures given above and from the value of the dissociation constant of the second hydrogen of phosphoric acid that if the concentration of hydrogen ion increases above its value in a microcosmic salt solution, the concentration of dihydrophosphate ion must increase greatly at the expense of monohydrophosphate ion. If there is any tendency for the occlusion of disilver hydrogen phosphate or monosilver hydrogen phosphate, the amounts of these salts occluded would be expected to depend on the concentration of the undissociated molecules of these salts in the solution, and therefore on the concentration of silver ion and on the concentration of monohydrophosphate or dihydrophosphate ion respectively.

The exact concentrations of the ions during the precipitation cannot be calculated, since the solubility of silver phosphate in slightly acid solutions and the solubility-product of silver phosphate are not known. It is, however, easy to understand from a study of the conditions under which the various samples of silver phosphate were precipitated, that these concentrations must have varied greatly in the preparation of the different samples and therefore constancy of composition gives a strong presumption that there is very little or no tendency for the occlusion of the undesired acid salts.

Samples N and O.—A 0.03 normal solution of silver nitrate was slowly poured into a 0.03 normal solution of disodium hydrogen phosphate with frequent shaking. This reaction may be roughly considered to take place in two stages represented by the equations:

$$3AgNO_3 + 2Na_2HPO_4 = Ag_3PO_4 + NaH_2PO_4 + 3NaNO_3$$
$$3AgNO_3 + NaH_2PO_4 = Ag_3PO_4 + NaNO_3 + HNO_3$$

At the beginning of the precipitation the solution is very slightly alkaline and remains very nearly neutral during the addition of the first half of the silver nitrate. The concentration of the silver ion is kept very low by the excess of phosphate and, therefore, little occlusion of the acid salts is to be expected in spite of the fact that the solution contains appreciable concentrations of the monohydrophosphate and dihydrophosphate ions. The precipitate during this stage is very finely divided and does not settle well and, therefore, no attempt was made to collect it separately.

During the addition of the second half of the silver nitrate the solution becomes slightly acid and the solubility of the silver phosphate increases rapidly. The precipitate settles readily. During the second stage the conditions are more favorable for the occlusion of the acid phosphate, but only a small amount of silver phosphate is precipitated during this stage.

After standing a short time the mother liquor was decanted from the precipitate, and exactly the calculated amount of redistilled ammonia, diluted to one liter, was added to neutralize the excess of acid and complete the precipitation. Since this sample was evidently produced from a solution which was slightly acid at the beginning of the precipitation, although very nearly neutral at the end, and since it contained a considerable amount of silver, the conditions were favorable for the formation of acid salts.

Both precipitates were transferred to a large platinum dish and washed many times by decantation with the purest water. This washing was prolonged over more than twenty-four hours in order to give time for all soluble matter to be leached out. When the precipitates were tested for nitrate with diphenylamine, negative results were obtained. Sodium was found to be absent by spectroscopic tests The precipitates were drained as far as possible in a platinum centrifugal machine, and the drying was completed by heating in platinum crucibles in an electric air bath for several hours, first at 90° and finally at about 130°. The dried lumps of silver phosphate were then gently ground in an agate mortar. The samples were preserved in platinum crucibles over sulphuric acid in the dark. All of the operations were performed in a dark room.

The sample prepared by pouring silver nitrate into disodium phosphate is designated Sample N, and the sample prepared by adding ammonia to the mother liquors is designated Sample O.

Sample P—A 0.03 normal solution of disodium ammonium phosphate was prepared by dissolving a weighed amount of disodium hydrogen phosphate and then adding the calculated amount of redistilled ammonia. The solution was then slowly poured into a 0.03 normal solution of silver nitrate. By this method of precipitation the solution is maintained as nearly neutral as is possible, because the excess of silver prevents the concentration of phosphate in solution from exceeding a very small value, so that neither can the solution become alkaline by hydrolysis nor can the concentration of hydrophosphate attain an appreciable value. The absence of the hydrophosphate ions would be expected to prevent the formation and occlusion of acid silver phosphate in this sample, whereas in Sample N the same result is probably brought about by the absence of the silver ion. Unfortunately both of these favorable conditions cannot be combined in one precipitation, as will be shown later. This precipitate settled readily. The washing, testing, and drying were carried out as already described for Samples N and O. This sample is designated Sample P.

Sample R.—A 0.03 normal solution of sodium ammonium hydrogen phosphate was slowly poured into a similar solution of an equivalent amount of silver nitrate. Under these conditions the solution contains an excess of silver, which tends to produce occlusion of acid phosphates, since the solution becomes more and more acid as the precipitation proceeds, and as the precipitation is therefore far from complete, the concentrations of the two hydrophosphate ions gradually approach a very considerable value. At no stage could the solution become alkaline by hydrolysis. It should be noticed that the procedure differs from that used in preparing Sample N in that the precipitate is formed in the presence of an excess of silver nitrate instead of an excess of phosphate, and that this difference in the method of mixing greatly changes the conditions of precipitation.

The precipitate, which was designated Sample R, coagulated and settled quite readily. The washing and drying were completed as usual.

It will be shown that samples of silver phosphate prepared under these various conditions have nearly, if not exactly, the same composition. Further proof of the absence of acid phosphate in these samples is given by experiments to be described later which show that no water is given off when this material is fused.

An attempt to prepare a sample by pouring silver nitrate into disodium ammonium phosphate yielded unsatisfactory results. Since the disodium ammonium phosphate solution was alkaline, owing to hydrolysis, it contained free ammonia, which prevented the precipitation of silver phosphate at first. Nearly one-quarter of the silver nitrate was added before a permanent precipitate was produced. At the end of the precipitation the solution was of course essentially neutral. Even after standing for four days the precipitate had not appreciably settled. Since the coagulation of the precipitate seems to occur much more readily in the presence of excess of silver, a considerable amount of silver nitrate in solution was added. The precipitate coagulated and settled immediately. It was washed and dried as usual. This sample was somewhat darker in color than the other samples and gave a large amount of insoluble residue when treated with dilute nitric acid. The analysis showed that it contained about two hundredths per cent. too much silver. This method of preparation is evidently unsatisfactory.

Three unsuccessful attempts were made to prepare silver phosphate from trisodium phosphate. The samples obtained in this way did not appear homogeneous after being dried and contained considerable sodium in spite of protracted washing. Two of these samples were found by analysis to contain, respectively, 4.4 and 4.1 per cent. less silver than pure trisilver phosphate. The third of these samples was so unsatisfactory in appearance and in its behavior during its preparation that it was not analyzed. This method of preparing silver phosphate is evidently not suitable for our purpose. Time was lacking to investigate further this anomalous behavior.

Method of Analysis.

Unfortunately, owing to the high melting point of silver phosphate, it was not feasible to fuse the silver phosphate before its analysis in order completely to eliminate all water. Instead it was heated in a platinum boat, in a current of pure dry air, at a temperature of about 400° for seven hours, and then by means of bottling apparatus[1] it was enclosed in its weighing-bottle without coming in contact with the moist air of the laboratory. During this heating the access of light to the sample was prevented. The continuous current of air which passed over the silver phosphate during the heating was driven by a water pump successively through an Emmerling tower containing beads moistened with silver nitrate solution, through a tower containing small pieces of fused caustic potash, then through three towers containing beads drenched with concentrated sulphuric acid, and finally through a long tube containing phosphorus pentoxide which had been resublimed in a current of air. The hard glass tube containing the platinum boat was surrounded by blocks of aluminium[2] which were jacketed with asbestos on the top and sides and heated directly from below by a large burner. The platinum boat was not attacked in the least, as was shown by the fact that its weight remained constant.

It was feared that in spite of this prolonged heating the silver phosphate still retained a trace of water, but by making the conditions in the different experiments as nearly uniform as possible it was hoped that the amount of water retained would be constant. Proof will be given later that the drying was highly efficient.

The salt thus prepared for analysis was allowed to stand over night in a desiccator covered with a black cloth in the balance room, and was then weighed in its glass-stoppered bottle by substitution, with the use of another weighing-bottle of very similar surface and volume as a counterpoise.

The balance was a nearly new No. 10 Troemner balance. It was easily sensitive to 0.02 mg. The weights had already been used in an investigation of the atomic weight of sulphur,[3] and were restandardized with a very gratifying result. None of the corrections found differed by as much as 0.02 mg. from those found a year before, and only a few by

[3] Richards and Jones, THIS JOURNAL, 29, 826 (1907).

0.01 mg. The balance was provided with a few milligrams of radium bromide of radioactivity 10,000 to dispel electrical charges generated during the handling of the weighing-bottles with cork-tipped pincers.

The platinum boat containing the silver phosphate was transferred to an Erlenmeyer flask of "non-sol." glass of one liter capacity and treated with about 30 cc. of 5 normal nitric acid. Solution took place rapidly. The solution was not perfectly clear, however, owing to a very slight insoluble residue which sometimes settled out on standing. The solution was then heated on a steam bath until the residue dissolved completely. Upon the addition of about one liter of cold water a very slight opalescence was produced, which was visible only when the solution was carefully examined in a very favorable light. The solution was again warmed until it became perfectly clear. The water and nitric acid used in these processes did not give an opalescence visible in the nephelometer when treated with silver nitrate. The nature of this residue will be discussed more in detail after describing the remainder of the analytical process.

About 800 cc. of water were placed in a large glass-stoppered precipitating flask and a very slight excess of hydrobromic acid was added from a burette. The silver phosphate solution was then very carefully poured into the hydrobromic acid solution. This method of precipitation gives less opportunity for the occlusion of silver phosphate or nitrate than the reverse method. The occlusion of hydrobromic acid can do no harm. The flask was shaken for twenty minutes and was allowed to stand for several days until the precipitate had completely settled. Then the precipitate was collected upon a weighed Gooch crucible after many rinsings with pure water. In order to protect the mat of the Gooch crucible from disintegration, it was covered by a circular disk of thin platinum foil, perforated with many small holes. The precipitate was dried in an electrically heated air bath for several hours at 90°, then for some time at 130°, and finally for at least eight hours at 180°. After the crucible containing the precipitate had been weighed, the silver bromide was transferred to a porcelain crucible and the loss on fusion determined. The presence of the platinum disk covering the mat makes it possible to transfer very nearly all the silver bromide to the porcelain crucible without contamination with asbestos and therefore it is unnecessary to correct the loss on fusion for the small amount of silver bromide which is not fused. The loss on fusion, which represents water remaining in the silver bromide, was subtracted from the weight of the silver bromide. The asbestos shreds carried away by the wash-waters and any silver bromide which may have escaped the Gooch crucible were collected by passing the filtrate through a very small filter paper. The paper was then burned and the residue, after treatment with a drop of nitric and hydrobromic acids to convert any reduced silver into silver bromide, was again gently heated and finally weighed. The weight of the asbestos, corrected for the ash of the paper, was added to the weight of the silver bromide. In order to determine the soluble silver bromide, the filtrate was evaporated until most of the excess of nitric acid was driven off. The precipitating flask and all the flasks which had held the filtrate were rinsed with strong ammonia and the rinsings added to the evaporated wash-water. Enough ammonia was added to make the solution alkaline and it was then diluted to 100 cc. in a graduated flask. The amount of silver bromide present was determined by comparison in the nephelometer with a very similar solution containing a known amount of silver bromide. Both precipitates were dissolved in ammonia and reprecipitated at the same time and under precisely similar conditions[1] in the nephelometer tubes by a slight excess of nitric acid. The amount found in this way was added to the weight of the silver bromide.

In order to determine whether silver phosphate is occluded by silver chloride, about 6 grams of silver phosphate were dissolved in nitric acid and the solution was diluted and poured into an excess of hydrochloric acid. After standing until the supernatant liquid was clear, the precipitate was washed very thoroughly with water and then dissolved in redistilled ammonia. The solution was diluted to one liter and the silver chloride was reprecipitated with nitric acid. The precipitate was filtered out and the filtrate evaporated in a platinum dish until concentrated. A little sodium carbonate was added and the dish was heated to expel all volatile ammonium salts. The residue was dissolved in about 3 cc. of water and treated with an excess of ammonium molybdate reagent with gentle warming. After standing for three days, not the slightest precipitate or yellow color had appeared, showing that no phosphate had been occluded by the silver chloride. Although not tested experimentally, it is reasonable to suppose that silver bromide also does not possess the property of occluding appreciable quantities of silver phosphate or phosphoric acid.

Insoluble Residue.

The presence of a slight residue or opalescence, after dissolving the dried silver phosphate in dilute nitric acid, proved the most perplexing difficulty which was encountered. The effort to discover the nature of this insoluble matter and eliminate it consumed a large part of the time devoted to this research. In an effort to make sure that it was not due to some unknown impurity, nineteen different samples of silver phosphate were prepared, the source of material, method of purification, and precipitation being varied. Disodium phosphate, trisodium phosphate, and sodium ammonium phosphate were carefully purified and converted into silver phosphate under varying conditions without appreciable effect upon the amount of the residue. Phosphorus oxychloride was twice fractionally distilled, converted into phosphoric acid, and then into disodium phosphate by means of sodium hydroxide made from sodium amalgam. The product was crystallized three times. Silver phosphate made from this material gave a slight residue, very similar to that obtained from the best samples made in other ways. Unfortunately, it was necessary to reject the analytical results obtained with this specimen because it was found to contain a small amount of metaphosphate. We did not succeed in preparing a sample of silver phosphate entirely free from the residue.

---

[1] See Richards and Staehler, This Journal, 29, 635 (1907).

In the meantime attention had been devoted to the residue itself. The small amount of material available rendered this part of the investigation difficult. The silver phosphate, after its precipitation and washing, but undried, dissolves in dilute nitric acid, giving a solution which is perfectly clear to the naked eye, although some samples gave a barely visible opalescence in the nephelometer. The opalescence was much too small to have any effect on the analytical results. The dried samples invariably gave an opalescence.

Dry silver phosphate is very slowly darkened in color by the action of light. This effect is even more pronounced when silver phosphate is exposed to the light in the presence of water. These darkened samples gave a much greater residue than the undarkened material. The residue was insoluble in ammonia, slowly soluble in dilute nitric acid, especially when heated, and readily soluble in strong nitric acid. The addition of hydrochloric acid to these nitric acid solutions gave a precipitate of silver chloride, while ammonium molybdate indicated the presence of phosphate.

In order to determine whether or not a loss of weight occurs during the darkening by light, a sample of silver phosphate was dried and weighed as usual and found to weigh 3.01901 grams. It was then exposed to the direct action of bright sunlight for a day, while contained in a weighing bottle which was placed in a desiccator over sulphuric acid. It was found to have darkened slightly in color and to weigh 3.01903. The gain of 0.02 mg. is within the limit of error in the weighing. This sample, when treated with dilute nitric acid, gave a much larger residue than usual, which weighed 1.8 mg. This is much more residue than was usually found in samples containing 4–8 grams of silver phosphate. It is estimated that the samples which had been protected from the action of light as much as possible, except when unavoidably exposed to diffused daylight while being weighed or transferred to the furnace and solution flask, contained about one one-hundredth of a per cent. of this residue.

Two analyses were made of the residue obtained by exposing silver phosphate *under water* to the action of light for several days, then dissolving the excess of silver phosphate in dilute nitric acid and thoroughly washing and drying the residue. 0.02674 gram of this residue yielded 0.03551 gram of silver chloride, which indicates that the residue contained 99.9 per cent. of silver. In the case of another sample of the residue prepared and analyzed in the same way, 0.04320 gram of residue yielded 0.05747 gram of silver chloride, which indicates that the residue contained 100.1 per cent. of silver. The mean of the two analyses is 100.0 per cent. of silver. These analyses prove conclusively that when silver phosphate is acted on by light in the presence of water, it is so altered (perhaps by the formation of a subphosphate similar to subchloride) that when treated with very dilute nitric acid metallic silver remains.

It does not follow, however, that it would be a correct procedure to determine the per cent. of this residue obtained from the samples used for analysis and apply a correction on the assumption that the material consisted of pure silver phosphate and a small amount of pure silver. This procedure would assume that the other product of decomposition is eliminated and not weighed. There are two facts which show that this assumption would be incorrect. In nearly every analysis, when the solution was diluted, after bringing the residue into solution by heating on the steam bath, a slight opalescence was produced. Careful tests of the water used showed that this opalescence was not due to impurity in the water. It seems probable that the substance which caused this opalescence was derived in part from the phosphate radical during the decomposition which produced the residue. The other fact is that dry silver phosphate does not lose weight when darkened by exposure to sunlight, although this treatment increases the amount of residue. The conclusion in regard to this residue may be summarized as follows: The washed moist silver phosphate was free from residue and contained silver and phosphoric acid combined in atomic proportions. During the drying and weighing a slight decomposition took place, undoubtedly owing in part at least to the action of light. It seems probable that during this decomposition no loss in weight took place, and therefore the sample contained the proper percentage of silver. When this slightly darkened silver phosphate is treated with cold, dilute nitric acid, the unchanged silver phosphate and perhaps also a portion of the altered material dissolve, leaving a slight opalescence, which in some cases is deposited as a very slight residue on standing. This residue is estimated to be about 0.01 per cent. of the weight of the silver phosphate. When the solution is warmed until perfectly clear, and then diluted, a very slight opalescence is usually produced which could be again cleared up by warming the solution. This opalescence is probably caused by the presence of the altered phosphate anion. If this explanation is correct, the presence of the residue cannot influence the result, and no correction need be applied. Until the exact nature of the decomposition products can be determined, there must remain some uncertainty in regard to whether or not any correction is necessary.

The uncertainty from this cause is, however, not very great. Even if all the phosphorus and oxygen corresponding to the residue of silver are removed before the weighing, the correction would be only 23 per cent. of the weight of the residue. If the residue amounts to 0.01 per cent., as has been estimated, the maximum correction would be 0.002 per cent. If part of the oxygen is lost, but the phosphorus remains, the correction would of course be smaller. If there is no loss in weight by the action of light on the dry silver phosphate, no correction need be applied. From the evidence so far obtained the latter assumption seems rather more probable than any of the others, and therefore no correction has been applied.

The Determination of Water in the Dried Silver Phosphate.

In order to find out how efficient the drying of the silver phosphate had been, experiments were made to determine the amount of water retained by silver phosphate which had been dried for analysis as described above (see page 308). The water was determined by fusing the dried phosphate in a current of dry air and collecting the moisture set free in a weighed phosphorus pentoxide tube. Since the melting point of pure silver phosphate is considerably above the softening point of hard glass, it was found advantageous to lower the melting point of the phosphate by the use of silver chloride as a flux.

About 15 grams of silver phosphate were placed in one end of a large silver boat and in the other end about 12 grams of previously fused silver chloride. The boat was then inserted in a hard glass tube and dried under the same conditions as prevailed in preparing the samples for the determination of the silver content. After the silver phosphate had been heated for seven hours in a current of purified air dried by phosphorus pentoxide, the air passing over the boat in the furnace was conducted through a weighed U-tube containing resublimed phosphorus pentoxide for one-half hour. This was done to make sure that all the water which had been liberated from the silver phosphate without fusion had been swept out of the apparatus. In no case was there a gain in weight during this process of more than 0.05 mg., which is about the limit of error in weighing the phosphorus pentoxide tubes. The backward diffusion of moisture was prevented by a second tube containing pentoxide.

The carefully weighed phosphorus pentoxide tube was again attached to the tube containing the silver boat with its charge of silver phosphate and silver chloride. The latter tube was then heated hot enough to fuse the silver chloride, which flowed down to the silver phosphate and readily caused the entire charge to fuse completely. The liberated water was swept into the phosphorus pentoxide tube by a current of dry air for about thirty minutes. The tube was then reweighed to determine the water evolved by the fusion of silver phosphate. The pentoxide tube was weighed by substitution for a very similar counterpoise tube, one stopcock of each tube being open during the weighing. Before being weighed both tubes were wiped with a damp cloth and allowed to stand near the balance for at least thirty minutes.

The following table gives the results of these experiments:

Sample	Weight of silver phosphate	Weight of water.	Per cent. of water.
P	13.50	0.00012	0 0009
P	15.64	0 00007	0.0004
O	15.66	0.00005	0.0003
O	16.62	0 00003	0.0002
		Average,	0.0005

The amount of water evolved is hardly greater than the probable error in weighing the phosphorus pentoxide tubes, and is less than the probable error in determining the amount of silver in the salt. We are therefore justified in concluding that the material which was used for the determination of silver was essentially free from water and that no correction need be applied to the results for inefficient drying.

This result also furnishes evidence that the samples are free from acid phosphates, which, owing to conversion into pyro- or metaphosphate, would evolve water when fused, although it is possible that occluded acid phosphates might have been converted into pyro- or metaphosphates during the drying. Sample O, which was prepared under conditions most favorable for the formation of the acid silver phosphate, does not appear to contain more water than Sample P, which was prepared under conditions which were unfavorable to the formation of acid phosphate. Since these two samples, which differed most widely in their method of preparation, showed no difference in the amount of water retained, it seemed unnecessary to test the other samples also. Unfortunately this method of detecting acid phosphate is not very sensitive, owing to the unfavorable relation of the atomic weights involved—one molecule of water corresponding to a deficiency of two atoms of silver.

The Specific Gravity of Silver Phosphates.

In order that the apparent weight of the silver phosphate might be corrected to the vacuum standard, the specific gravity of this salt was found by determining the weight of toluene displaced by a known quantity of salt. The specific gravity of the toluene at 25° referred to water at 4° was 0.8633. Great care was taken to remove air from the salt when covered with the toluene by warming the pycnometer, then placing it in a vacuum desiccator and boiling the toluene under reduced pressure. The salt and toluene were mechanically stirred to assist the escape of air bubbles. This process was repeated several times.

Weight of silver phosphate in vacuum. Grams	Weight of displaced toluene in vacuum. Grams	Volume of silver phosphate cc	Density of silver phosphate. 25°/4°.
22.955	3.113	3.606	6.366
16.942	2.205	2.658	6.374
		Mean,	6.37

Therefore the apparent weight of silver phosphate was corrected to the vacuum standard by adding 0.000044 gram per gram of salt. Similarly 0.000041 gram was added for every gram of silver bromide.

The Adsorption of Air by Silver Phosphate.

Since the silver phosphate was in a very finely divided condition and since many fine powders have the power of adsorbing appreciable quantities of air or other gases, the possibility of the adsorption of air by silver phosphate was investigated. The method of experimenting and the apparatus were very similar to that used by Baxter and Tilley for investigating the behavior of iodine pentoxide

"Two weighing bottles were constructed with long, very well ground stoppers which terminated in stopcocks through which the tubes could be exhausted. These tubes were very closely of the same weight and very nearly the same internal capacity. The tubes were first exhausted and compared in weight by substitution. Next they were filled with dry air and again weighed, the weighing being carried out with stopcocks open. Both steps were then repeated with essentially the same results."[1]

In these two experiments, when air was admitted, the counterpoise gained 0.00028 and 0.00021 gram respectively (average 0.00025) more than the tube which was later to contain the silver phosphate. After 22.69 grams of pure dry silver phosphate had been placed in the tube the tube and its counterpoise were exhausted and the difference in weight determined. When dry air at 25° and 766 mm. was admitted to both the tube containing the silver phosphate and the counterpoise, the counterpoise gained 0.00443 gram more than the tube. Therefore the air displaced by the silver phosphate was 0.00443 — 0.00025 = 0.00418 gram. Since 22.69 grams of silver phosphate of density 6.37 have a volume of 3.56 cc., the volume of pure air displaced at 25° and 766 mm. should weigh 0.00425 gram.[2]

---

[1] Baxter and Tilley, This Journal, 31, 214 (1909).

[2] Rayleigh's value for the density of air at 0° and 760 mm., 1.293 grams per liter, is used. *Proc. Roy. Soc.*, 53, 147.

The experiment was then repeated. After the air had been exhausted from the tube and its counterpoise, the tube containing the silver phosphate was heated gently. No gas was evolved. The tube and its counterpoise were then weighed by substitution. When dry air at 24.5° and 767 mm. was admitted to both, the counterpoise gained 0.00445 gram more than the tube containing the silver phosphate. Therefore the air displaced by the silver phosphate was 0.00445 — 0.00025 = 0.00420 gram, whereas the weight of air displaced, calculated from the density of the salt, is 0.00426 gram.

The agreement between the experimental results and those calculated from the density of silver phosphate on the assumption that no adsorption takes place is close enough to show that no significant amount of adsorption occurs.

Discussion of the Results.

The following table contains all of the analyses not vitiated by a known impurity in the sample or by an accident during the analysis. One feature of this table requires further explanation. In Analysis 5 the silver was determined by precipitation as chloride instead of bromide. For every gram of silver phosphate there was obtained 1.02707 grams of silver chloride. Since Baxter found AgBr : AgCl = 1.31017 : 1.00000,[1] this analysis indicates that 1 gram of Sample N is equivalent to 1.02704 × 1.31017 = 1.34560 grams of silver bromide. This result is placed in the table for comparison with the other analyses and is used in the computation of the mean.

1	O	6.20166	8 34427	0.00036	0.00034	0.00007	8.34490	1.34558
2	O	6.35722	8.55386	0.00041	0.00003	0.00011	8.55419	1.34559
3	N	5.80244	7.80792	0 00029	0.00005	0.00007	7.80819	1.34567
4	N	5.05845	6.80658	0.00019	0.00020	0.00012	6.80685	1.34564
5	N	3.34498	(AgCl) 3.43514	0.00029	0.00009	0.00008	(AgCl) 3.43544	1.34560
6	P	7.15386	9.62648	0.00046	0.00013	0.00013	9.62694	1.34570
7	P	7.20085	9.68929	0.00023	0.00005	0.00010	9.68947	1.34560
8	R	6.20182	8.34466	0.00041	0.00027	0.00012	8.34522	1.34561
9	R	5.20683	7.00543	0.00029	0.00040	0.00007	7.00605	1.34555

Average, 1.34562

Per cent. of Ag in Ag_3PO_4, 77.300

A careful study of these results shows that the composition of silver phosphate is very nearly, if not quite, independent of the changes in the acidity of the solutions from which it is precipitated. Samples O and R were prepared under slightly more acid conditions than Samples N and P. The average amount of silver bromide obtained from 1 gram of Samples O and R is 1.34558 (77.297 per cent. of silver), whereas the average from Samples N and P is 1.34564 (77.301 per cent. of silver). This difference, if real and significant, is probably due to a very slight occlusion of disilver hydrogen phosphate by samples O and R. It does not seem probable that any basic salt was present in Samples N and P, because silver shows little tendency to form basic salts and the conditions of precipitation were not favorable for the formation of basic salts.

---

[1] THIS JOURNAL, 28, 1322 (1906).

The difference between composition of the samples is so slight, both in absolute amount and by comparison with the differences between different analyses of the same sample, that in the present state of our knowledge it does not seem justifiable to reject the analyses of Samples R and O. This conclusion is supported by the fact that the water determinations failed to show a difference between these samples. The results, however, indicate that the average ratio 1.34562 (77.300 per cent. of silver) may be slightly too low, owing to the presence of disilver hydrogen phosphate. The ratio 1.34562, assuming the atomic weight of silver to be 107.88, and assuming that silver bromide contains 57.4453 per cent. of silver, leads to an atomic weight of 31.043 for phosphorus, whereas the ratio 1.34564 derived from Samples N and P gives the value 31.037. The rounded-off value, 31.04, may be considered to be essentially free from error from this source. With values for the atomic weight of silver of 107.87 and 107.86, the atomic weight of phosphorus becomes 31.03 and 31.02 respectively.

Owing to the high molecular weight of silver phosphate and to the small percentage of phosphorus, a given percentage error in determining the ratio of silver bromide to silver phosphate is multiplied over thirteen times in the atomic weight of phosphorus. Thus while the extreme values for the ratio differ by only a little over one one-hundredth of a per cent., the values for the atomic weight of phosphorus differ by fifteen hundredths of a per cent., or 0.047.

We are greatly indebted to the Carnegie Institution of Washington for generous pecuniary assistance in pursuing this investigation; also to the Cyrus M. Warren Fund for Research in Harvard University for many pieces of platinum apparatus.

Summary.

1. A careful study has been made of the conditions necessary for the preparation of pure trisilver phosphate.

2. It is found that silver phosphate can be almost completely dried without fusion by heating in a current of dry air.

3. The density of silver phosphate is found to be 6.37.

4. It is found that silver phosphate does not adsorb a significant amount of air.

5. Nine analyses, made with four different samples, show that 1 gram of silver phosphate yields 1.34562 grams of silver bromide, whence the per cent. of silver in silver phosphate is 77.300.

Therefore,

If Ag = 107.88 P = 31.04
If Ag = 107.87 P = 31.03
If Ag = 107.86 P = 31.02 .

CAMBRIDGE, MASS., November 12, 1909.

THE SOLUBILITY OF GOLD IN NITRIC ACID.[1]

BY FREDERIC P DEWEY.

Received December 29, 1909

If there is any statement that is firmly established in general chemical literature it is that gold is not soluble in any single acid. In the literature of assaying, however, may be found various statements to the effect that, in parting gold from silver in assaying, gold may go into solution in the nitric acid used.

Makins[2] boiled a series of samples of parted gold in nitric acid of two different strengths and found an increasing loss of gold depending upon the amount of boiling, but he did not establish the purity of the acid used, nor the presence of gold in the acid after boiling. Neither did he determine the amount of silver remaining in his cornets.

In discussing the causes of loss of gold in making gold bullion assays, Rose[3] states that 8 per cent. of the loss is due to the gold going into solution in the nitric acid during parting. This statement is apparently based upon the author's own work, but no details are given to explain or sustain it.

Rickets and Miller[4] quote this statement from Rose without comment.

In his latest book Rose,[5] immediately after the general statement that gold is not perceptibly attacked by nitric acid, adds that finely divided gold is slightly soluble in boiling nitric acid, but gives no experimental data.

In speaking of the silver remaining in the gold after parting, Lodge[6] says, "If strong nitric acid (1.42 sp. gr.) is used this amount of silver may be slightly reduced, but the gold will begin to dissolve." However, he gives no data upon the subject.

[5] "Precious Metals," p. 14.

[6] "Notes on Assaying," p. 144.

Hillebrand and Allen,[1] after reviewing various previous statements upon the subject, describe their own tests, which tended to show that parted gold was slightly soluble in nitric acid. Their results, however, are not conclusive, for, while we may assume that reasonable precautions were taken to insure the purity of the acid used, these precautions are not stated and, while the utmost care was taken to guard against loss by float gold, yet invisibly fine particles of gold may have been suspended in the acid. It would have been better if the solutions had been filtered before evaporation, and if the porcelain dishes containing the residue after evaporation had been gently heated with a few drops of aqua regia, and a small amount of strong hydrogen sulphide water added, and the solution filtered off before the dishes were wiped out with filter paper, adding the filter to the wiping paper before cupelling. Again, in testing the parting solutions for gold, no tests are given to show the freedom of the separated silver from gold.[2]

The chief difficulty militating against the certainty of the results in experimenting upon this subject lies in the minute quantities involved when only small quantities of gold are employed for the tests.

For a long time I have been engaged upon an extensive investigation into the accuracy of gold bullion assays. A preliminary paper giving the figures obtained in comparing many hundred assays was read at the Seventh International Congress of Applied Chemistry at London, May 27 to June 3, 1909, and at the Spokane meeting of the American Institute of Mining Engineers.[3] This paper will also be published in the forthcoming report of the Director of the Mint for the fiscal year ended June 30, 1909.

In following up this matter by an investigation into the conditions surrounding and affecting the accuracy of the work of making a gold bullion assay, the possible solubility of the gold in the nitric acid during parting becomes an important point. My preliminary results were so decisive that the work was somewhat extended and it was found easy enough to thoroughly demonstrate this solubility when large amounts of gold were employed and to dissolve finely divided gold in boiling nitric acid of 1.42 sp. gr. with only a small amount of gold.

A few tests made upon regular assay work will suffice here. The acid from parting nine fine gold assays was treated with a very small amount of hydrochloric acid, the precipitate filtered off and assayed, yielding 0.33 mg. of gold. To the filtrate a small amount of lead acetate was added and then sulphuric acid. The whole was evaporated to fumes, the residue filtered off and assayed, yielding 0.04 mg. of gold.

---

[1] Comparison of assays, "Gold Telluride Ores," *Bull.* 253, U. S. Geological Survey, p. 27.

[2] Prof. Hillebrand wishes me to state that the acid used by them was 1:1.

[3] *Bull. Am. Inst. Mining Eng.*, August, 1909, p. 705.

The acid from nine coin proof assays was allowed to stand several days, when it was filtered and the filter paper was assayed, yielding 0.29 mg. of gold. To the filtrate a small amount of hydrochloric acid was added and the precipitate assayed showing 0.02 mg. of gold. A second treatment with hydrochloric acid gave no gold.

The acid from nine coin proof assays was filtered when nearly cold and the filter yielded 0.26 mg. gold. On standing two days and filtering again 0.16 mg. of gold were recovered. Treatment of the second filtrate with a very slight amount of hydrochloric acid failed to give any more gold.

In our regular assay work we boil the cornets twice in 1 : 1 acid for 10 min. each time and then in 3 : 2 acid for 10 min. In the next test on nine coin proof assays the acids were kept separate. On filtering, when cool, not cold, Nos. 1 and 2 gave only questionable indications of gold while No. 3 yielded 0.02 mg. of gold. On standing 3$^1/_2$ days and filtering, No. 1 gave no visible gold, No. 2 only the faintest specks, while No. 3 gave 0.14 mg. of gold. On treating the filtrate with a very slight amount of hydrochloric acid, Nos. 1 and 2 gave no gold, but No. 3 gave 0.02 mg. gold. On treating the second filtrates with a small amount of hydrogen sulphide water all three samples failed to show gold.

While these results may appear to be somewhat confused, yet they show conclusively that the acid from the parting carries gold, that, while the gold is not visible, yet some of it may be removed by filtering and that even after standing and filtering again gold may still be recovered from the filtered acid.

This state of affairs might give rise to considerable speculation as to just what the action of the acid on the gold might be, but I pass to further more elaborate and more conclusive tests.

As the amounts of gold recovered in the tests upon our regular assay work were so small I prepared some special melts of metal, approaching the composition of our regular assay buttons, but containing differing proportions of silver, and loaded the parting basket in one case to its utmost capacity. The small bars were rolled out thin, with frequent annealing, cut into strips and put into the regular cups in the basket.

The first metal contained about 20 grams of gold, 46 grams of silver, a little copper and less lead. This sample was boiled three times for ten minutes each in the dilute acid and twice in the stronger acid. A total of 1.30 mg. of gold was recovered from the fifth acid. The cornets remaining after this prolonged boiling weighed 20.61 grams and contained 22.36 mg. silver.

The nitric acid used in the tests so far described was taken from the regular laboratory supply and, while I have no especial reason for doubting its integrity, for the next test the acids were especially prepared by treating a large conical flask of each strength with a little nitrate of silver and allowing them to stand at rest for over a week before using them.

The second metal consisted of 25.03 grams of cornet gold, 63.7 grams of silver, 0.125 gram copper and 0.075 gram lead. This sample was boiled four times in the dilute acid and three times in the stronger acid for varying lengths of time, and then given a fifteen-minute boil in the full strength of 1.42 sp. gr. acid. The acid from the last boil was colored distinctly yellow. After standing four days, the acid from the seventh boil, which was 15 minutes in 3 : 2 acid, was filtered and the filter showed 0.12 mg. of gold, while the filtrate showed 1.48 mg. of gold.

The gold was then boiled in a tall plain beaker in 1.42 acid from the laboratory stock for a full hour, producing about 500 cc. of a yellow solution, carrying gold at the rate of 77.2 mg. per liter.

The gold was then boiled in 1.42 acid from the laboratory stock for two hours producing about 600 cc. of a bright yellow solution, carrying gold at the rate of 183.3 mg. per liter.

The cornets remaining after this drastic treatment weighed 24.83 grams and carried 6.38 mg. of silver.

A third metal was prepared from 30 grams of cornet gold, 80 grams silver, 0.15 gram copper and 0.08 gram lead, but this was a little more than the platinum basket would hold. As this metal contained rather a large proportion of silver it was cautiously treated with the dilute (1 : 1) acid to remove the silver with only a small amount of disintegration of the gold. It was then boiled nearly an hour in the stronger (3 : 2) acid.

As a quicker and more certain precaution against the possible presence of chlorine in the nitric acid, the 1.42 acid next used was boiled in the beaker at about 120° for about two hours before the introduction of the gold, after which the boiling was continued for a trifle over three hours, producing nearly 700 cc. of a bright yellow solution, carrying gold at the rate of 186.4 mg. per liter.

The next test was made in the platinum parting apparatus. About 300 cc. of acid were boiled for an hour, the gold introduced, and the boiling continued for another hour. This solution contained 26.69 mg. of gold, or about 175 mg. per liter.

A final crucial test was carried out in the platinum parting apparatus with every possible precaution. I personally opened, with the utmost care, a fresh bottle of nitric acid of the J. T. Baker Chemical Company's make, bearing the following analysis:

Specific gravity...........	1.415–1.42
Nitric acid...............	69–70 per cent.
Sulphuric acid............	None.

Hyponitrous acid	None
Chlorine	"
Iodine	"
Iron	0.0002 per cent.
Non-volatile matter	0.001 "

Lot No. 7127.

The whole platinum boiling apparatus was thoroughly cleaned and rinsed out twice with this acid and all the acid used was poured directly from the bottle into the platinum. At no time during the test was the acid allowed to come into contact with glass after leaving the original bottle.

Some of the acid was boiled about forty-five minutes and the platinum basket containing the gold used in the previous test was soaked in this acid about two hours. About 300 cc. of the acid were boiled in the second platinum dish 45 m., when the platinum basket containing the gold was introduced and the boiling continued. As the joint between the platinum dish and the platinum cover is poor there was necessarily considerable evaporation of the acid and when the gold began to stick out of the acid the boiling was stopped, the gold having been boiled a little less than two hours.

It is estimated that the solution when cold would have been about 130 cc., but the hot solution was diluted a little, poured off from some small pieces of mechanically separated gold and allowed to stand over night. In the morning the cold solution was filtered and the filter caught 0.66 mg. of gold. The filtered solution showed 86.31 mg. of gold or at the rate of over 660 mg. per liter.

The remaining gold is still in use preparing a strong solution with a new lot of acid to be used for some stability tests. On December 27th, 25 cc. of this solution showed 4.94 mg. of gold. On January 27th, there was a slight scum of gold on the surface of the liquid of which 5 cc. showed 4.94 mg. of gold. . The final weight amounted to 28.724 grams and contained 3.06 mg. of silver, 0.29 mg. of copper and traces of lead.

As a further test, proof gold, made with great care at the Philadelphia Mint as described by McCaughey,[1] was rolled out very thin and boiled in a conical flask for five hours in previously boiled nitric acid from the freshly opened bottle of Baker's acid mentioned above. The strip exposed about seven square inches of surface to the acid. An accident caused some loss of the dissolved gold, but 11.58 mg. were recovered from the solution.

My personal opinion is that the temperature required to boil 1.42 acid (120°) has fully as much, if not more, to do with dissolving the gold than the strength of acid employed.

The method followed in determining the gold in the strong solutions consisted in evaporating to dryness, digesting gently with a little aqua regia, adding a liberal amount of strong hydrogen sulphide water, and, after gentle heating, adding some nitrate of silver solution, so that the sulphide of gold would be enclosed and protected by the sulphide of silver. The sulphides were filtered off, put into a porcelain crucible and the filter burned off carefully. The metallic sponge remaining was enclosed in a small cornucopia of sheet lead, more silver added and cupelled.

---

[1] THIS JOURNAL, 31, 1262.

After trying various methods of gathering a little gold out of a solution containing much silver, I have come to prefer strong hydrogen sulphide water as it is a most excellent precipitant for the gold and the co-precipitated silver protects the gold in the subsequent operations, which are simplified for the sulphide precipitate over a chloride of silver precipitate. In practice a limited amount of the hydrogen sulphide water is added to the solution, which is allowed to stand, with occasional stirring, a day or two, before filtering.

It is a very easy matter to exhibit the solubility of finely divided gold in strong nitric acid. By alloying a small piece of gold with $2^1/_2$–3 times its weight of silver, and dissolving out the silver in diluted nitric acid the gold will be left in good condition for such a test. Five minutes' hard boiling in a few cubic centimeters of strong nitric acid, which may have been previously boiled if desired, will give a distinctly yellow solution, which may be further tested for gold.

The discussion of the application of these results to the question of gold bullion assaying is reserved for a future paper on the general subject of the accuracy of such assaying, but I would say that the practical conclusion of Hillebrand and Allen,[1] that the solubility of the gold in the parting acid in ordinary ore assaying is negligible, is undoubtedly sound, unless the ores be most unusually rich in gold, but the excessive boiling in nitric acid sometimes used by them in their tests might dissolve an appreciable amount of gold in very rich ores and even this drastic treatment is not entirely sure to remove all of the silver, unless more than three parts of silver to one of gold were present originally.

HALIDE BASES OF TANTALUM.

BY WILLIAM H. CHAPIN.

Received January 17, 1910.

Preparation of a Lower Bromide of Tantalum from the Pentabromide.

While attempting to produce a lower bromide of tantalum by reduction of the pentabromide in hydrogen, Van Haagen[2] obtained a small amount of a new green compound which he found to possess very remarkable properties. It dissolved in water without decomposition, and it suffered no change even when its solution was boiled or evaporated in the open. In the solid state it was perfectly stable in the air. Moreover it possessed remarkable tinctorial powers, a few milligrams being sufficient to color several hundred cubic centimeters of water a bright emerald-green. Also a piece of silk dipped in its solution afterwards possessed a delicate green color which was not removed by washing. With ammonia the compound gave a brown hydroxide, which on exposure to the air became white. What the structure of the new bromide was Van Haagen was not able to determine because of lack of time and material, but an analysis attempted on a very small sample pointed to something approaching a tribromide.

---

[1] *Loc. cit.*

[2] Thesis, "Tantalum and Some of Its Halides," Univ. of Pa., 1909.

A few months later while engaged in the preparation of material for further investigation, we noticed the announcement of a new chloride of tantalum by Chabriè.[1] The properties of this compound, as described by its discoverer, corresponded in almost every detail with those of Van Haagen's bromide. The method of preparation, however, was entirely different, consisting essentially in the reduction of tantalum pentachloride in the dry way by means of sodium amalgam. Chabriè noted the crystalline form of his chloride, and also by means of the spectroscope proved its identity as a compound of tantalum. Owing to scarcity of material, however, he, too, gave but a single analysis; but from the results obtained believed himself justified in ascribing to the compound the formula $TaCl_22H_2O$.

A method being needed by which to prepare the bromide in larger quantity, Chabriè's announcement was welcome, and upon trial it was found that the method could be used with fair success. It finally was the only method used, although it was found to yield better results after slight modification. The following is an outline of the procedure: One part of tantalum pentabromide was mixed with four parts of 3 per cent. sodium amalgam, and the mixture quickly introduced into a combustion tube of hard glass. The air was then exhausted by means of a water pump, and the tube gradually heated, finally to redness. The reduction product was allowed to cool completely in a vacuum, and was then removed and thrown into water acidulated with hydrobromic acid. The by-products were filtered off, and the intensely green solution concentrated on the water bath until the acid present finally caused the compound to separate as a crystalline powder, leaving the supernatant liquid of a yellowish color. This powder was removed, washed with hydrobromic acid, and finally dried on a water bath.

The yield of the green bromide obtained by this method was always very slight, averaging only about 15 per cent. of the theory. Altogether 20 grams were obtained, and to do so 200 grams of the pentabromide were used. Just what this means can be appreciated by one who has made 200 grams of pure tantalum pentabromide. Fortunately the compound as first obtained was remarkably pure, and for that reason there was no necessity for repeated crystallizations and consequent loss of material.

---

[1] *Compt. rend.*, 144, 804 (1907).

The by-products mentioned above were important since they represented by far the larger part of the tantalum used. They seemed to consist of some lower oxide. While wet they were of a brown color, but upon drying became gray, and upon strong ignition they became pure white, and appeared then to be ordinary tantalum oxide. As will be shown later these by-products were turned to good account in establishing the identity of the bromide.

Some of the properties of this green bromide have already been mentioned, among them its high coloring power. As evidence of this it might be mentioned that a solution containing 1 gram per hundred cubic centimeters possessed such an intense color that a layer half an inch thick was perfectly opaque. Examined under the microscope the substance was found to consist of beautiful hexagonal crystals. No crystals over 0.25 mm. in diameter were ever seen, but they were often very brilliant, causing the powder to sparkle when placed in the sunlight. As ordinarily prepared the compound was black, but if ground down in a mortar it became dark green in color.

Identification of the Bromide as a Compound of Tantalum.

Although Chabriè had shown his chloride to be a tantalum compound it was not thought superfluous to obtain definite proof as to the identity of the new bromide. To this end the oxides mentioned above as "by-products" were collected and converted into the pentabromide. This was then reduced by means of sodium amalgam, producing a fresh yield of the green bromide, and of course more of the "by-products." The latter being collected, the process was repeated until finally the residue obtained was too small in amount to work with. If the bromide were not a tantalum compound the yield should have grown smaller each time the cycle was repeated, until finally a residue was obtained which would not respond to the reaction. No such diminution in the yield was noticed, however.

As further proof of the identity of the new bromide a portion was decomposed, and converted into the well-known double fluoride, K_2TaF_7. The product thus obtained possessed all the characteristic properties of this salt; and carefully conducted analyses failed to disclose any difference, as the following results will show:

K as K_2SO_4	Found	44.32,	Calculated	44.46 per cent.
Ta as Ta_2O_5	Found	56.40,	Calculated	56.32 per cent.

These results serve to confirm those mentioned in the last paragraph, and are to be accounted for only by assuming that we are here dealing with a tantalum compound.

Structure of the Bromide.

As has already been mentioned Chabriè regarded his compound as a dichloride, $TaCl_2 2H_2O$; and considering the close similarity of the two bodies there seemed no reason to doubt that the bromide would be found to possess an analogous structure, as represented by the formula $TaBr_2 2H_2O$. However, as the following example will show, the results of the analyses did not agree with this supposition:

	Found, per cent.	Calculated, for $TaBr_2 2H_2O$, per cent.
Ta	46.60	48.01
Br	48.06	42.44
H_2O	5.46	9.55
	100.12	100.00

The methods used for the analyses were very simple. The tantalum was precipitated from the boiling solution by means of ammonia, and subsequently ignited to the oxide Ta_2O_5. For the determination of the bromine one of two methods was employed: *first*, the filtrate from tantalum was acidified with nitric acid, and the bromine precipitated as silver bromide; or *second*, the filtrate from tantalum hydroxide was simply evaporated to dryness in a weighed porcelain crucible, and the residual ammonium bromide dried to constant weight in an oven at 100°. The results obtained by use of these two methods were surprisingly concordant, the maximum variation being less than 0.1 per cent. After the second method had been thoroughly tested it was given the preference, since its use permitted the application of a very simple check on the tantalum value. This consisted in the decomposition of the ammonium salt by means of nitric acid, and subsequent weighing of a very slight residue of oxide which had escaped the filter. It may be mentioned that this residue never in any case exceeded 0.2 mg. and in most cases was much less than this. The ammonium bromide could, of course, have been expelled simply by heating, but this procedure would almost certainly have caused the expulsion of the tantalum residue, either mechanically or otherwise. The values for tantalum as thus obtained were very concordant, the maximum variation in a series of five analyses being 0.1 per cent.

The percentage of water in the bromide was determined by mixing with litharge to retain the bromine, placing the mixture in a porcelain boat, and then heating in a combustion tube in a current of air, the water being collected in a calcium chloride tube. Three determinations made after this manner gave the following percentage: 5.40 per cent., 5.50 per cent., 5.50 per cent. or an average of 5.46 per cent. It was found impossible to determine the water without the use of the litharge, since the compound invariably broke down, giving off hydrobromic acid before all the water was expelled.

When, after repeated analyses, it was seen that the composition of the compound as first obtained did not correspond to that of dibromide it was thought that it might not be a single substance, but a mixture of two substances, for example the dibromide and the tribromide. With this in mind the whole stock of the bromide was recrystallized in such a way as to separate it into several fractions. In this way it was hoped to cause at least a partial separation of the different compounds if more than one were present. However, upon analyzing the different fractions, absolutely no difference could be detected, and the notion that the substance was not homogeneous had to be abandoned.

Accepting the results of the analysis as final, an empirical formula was calculated; thus, $Ta_6Br_{14}7H_2O$ for which the exact values would be:

	Per cent
Ta	46.58
Br	48.01
H_2O	5.41

Comparison of these values with those obtained from analysis will show a remarkably close agreement.

It scarcely seemed possible that all these fourteen atoms of bromine could exist in the same relation to the tantalum. The more likely possibility seemed to be the presence of a complex, in which a part of the bromine would be more loosely bound than the rest. To test this possibility the solution of a weighed amount of the bromide was treated with silver nitrate, the reaction being carried out in the cold to prevent decomposition. In two such determinations the percentages of bromine obtained were respectively 7.02 and 6.76, an average of 6.89. Now the total percentage of bromine corresponding to fourteen atoms was, as already shown, 48.06. Of this the above value is almost exactly one-seventh, and therefore corresponds to *two atoms*. To make the formula agree with the experimental data, then, it should be written $(Ta_6Br_{12})Br_27H_2O$. In water solution the molecule is undoubtedly divided into a positive complex ion and two negative bromine ions.

As further evidence of the nature of the bromide its molecular weight was determined both by boiling point and freezing point methods. For the boiling point method propyl alcohol (b. p. 99°) was chosen as the best available solvent. Using 1 gram of the salt in 16 grams of solvent the observed rise in two experiments was respectively 0.055 and 0.059°, corresponding to apparent molecular weights of 1800 and 1700, or an average of 1750. Now, an ordinary salt when dissolved in propyl alcohol in the proportion used in this experiment is dissociated to the extent of about 15 per cent. Allowing, then, for *15 per cent. dissociation*, an observed *molecular weight of 1750*, and *three ions* to the molecule, the true molecular weight may be calculated with a fair degree of certainty by use of the formula, $M = Mo(x(n - 1) + 1)$ where Mo = the observed molecular weight, x = the degree of dissociation, and n the number of ions per molecule, thus $M = 1750\ (0.15(3 - 1) + 1) = 2275$. The molecular weight calculated from the formula is 2332.

A freezing point determination, using water as the solvent, gave the following results: 1 gram of the salt in 16 grams of solvent gave a lowering of 0.162°, corresponding to an apparent molecular weight of 720, or about one-third the true molecular weight. This was exactly the result expected, since in water solution at the dilution here employed ordinary salts are almost completely dissociated.

Now, bringing together the facts stated in this section: Analysis has shown that the new green compound is not a dibromide, but that its different constituents are present in the proportions represented by the formula $Ta_6Br_{14}7H_2O$. The reaction with silver nitrate indicates that in water solution one-seventh of the bromine is in the ionic condition. This should be indicated by writing the formula $(Ta_6Br_{12})Br_27H_2O$. Molecular weight determinations by both freezing point and boiling point methods point to a molecule of approximately the same size as that indicated by the empirical formula. Hence it is believed that this is the true formula of the compound.

Replacement of the Ionized Bromine.

As would probably be expected it was found possible to replace the two ionized bromine atoms by other halogens, by hydroxyl, and by almost any acid radical. Replacement of bromine by hydroxyl was effected by treating a weighed amount of the salt (in solution) with just sufficient standard sodium hydroxide solution to complete the reaction:

$$(Ta_6Br_{12})Br_2 + 2NaOH = (Ta_6Br_{12})(OH)_2 + 2NaBr.$$

The hydroxide separated in crystalline form, and being only slightly soluble in water, left the solution nearly colorless. Analysis showed it to be $(Ta_6Br_{12})(OH)_210H_2O$. It was soluble in alcohol, insoluble in ether, consisted of thin hexagonal plates, and was stable in the air below 100°.

The replacement by chlorine could be brought about by dissolving the hydroxide in hydrochloric acid, but was most easily effected by simply evaporating a solution of the bromide with hydrochloric acid. The interesting point about this reaction was the fact that only two atoms of bromine were replaced, even when concentrated acid was used and the evaporation repeated four times. That the chlorine took the place of the ionized bromine was proved by the fact that treatment of the resulting mixed halide with silver nitrate or sulphate produced a precipitation of silver chloride containing no bromide. The formula of the compound, as shown by analysis, is $(Ta_6Br_{12})Cl_2 7H_2O$.

Replacement of bromine by iodine was effected by first preparing the hydroxide, and then dissolving this in hydriodic acid. Its formula is $(Ta_6Br_{12})I_2 7H_2O$.[1]

After following the bromide through these various transformations it becomes evident that a certain part of the molecule (Ta_6Br_{12}) acts like a single element or *base*, passing unchanged through a whole series of compounds. It is therefore proposed that this be given the name *bromotantalum*. The original compound $(Ta_6Br_{12})Br_2 7H_2O$ will then be called *bromotantalum bromide*, and the other compounds mentioned above will be respectively, *bromotantalum hydroxide*, *bromotantalum chloride*, and *bromotantalum iodide*.

Chabrie's Chloride.

As already mentioned the properties of Chabriè's chloride correspond very closely with those of the bromotantalum compounds. Even the crystalline form was identical. These facts made it seem highly probable that the formula should be $(Ta_6Cl_{12})Cl_2 7H_2O$ and not $TaCl_2 2H_2O$, as Chabriè writes it. Having only a very small amount of material to work with, which at the same time may not have been pure, he could easily have made such a mistake. Moreover, Chabriè determined the water in his compound by simply heating in an atmosphere of carbon dioxide, or at least he does not mention having used a retainer for the chlorine. This procedure would certainly not succeed in case of the bromide, and may account for a high value for water and a low value for chlorine.

To settle the matter we prepared the chloride according to Chabriè's method and, upon analysis, obtained the following values:

	Found, per cent.	Calculated for $(Ta_6Cl_{12})Cl_2 7H_2O$, per cent.
Ta	63.80	63.58
Cl	29.40	29.03
H_2O	7.20	7.37

Chabriè reports the following:

	Found, per cent.	Calculated from $TaCl_2 2H_2O$, per cent.
Ta	63.83	63.1
Cl	23.85	24.4
H_2O	12.22	12.5

It should be noted that his most reliable value—the value for tantalum,

---

[1] For further details regarding these mixed compounds refer to the author's thesis "Halide Bases of Tantalum," Univ. of Pa., 1909.

—agrees much more closely with the complex formula than with the simple one, and the other values can be accounted for as mentioned above. His chloride is therefore without doubt the exact analogue of the bromotantalum bromide, and should be called "chlorotantalum chloride."

UNIVERSITY OF PENNSYLVANIA.

METALLIC TITANIUM.

BY M A. HUNTER.

Received January 19, 1910.

All the earliest attempts at the preparation of metallic titanium resulted for the most part in the production of the various nitrides which from their metallic appearance were always mistaken for the metal. Thus Wollaston[1] mistook the cyanonitride which is frequently found in the slag and metal from the blast furnace for the metal. Again Berzelius[2] reduced potassium titanifluoride with potassium and obtained a black powder which on polishing showed a metallic streak. This substance was insoluble in hydrofluoric but easily soluble in a mixture of hydrofluoric and hydrochloric acids and whatever it may have been it certainly was not metallic titanium, for titanium is immediately soluble in hydrofluoric acid. Rose[3] produced a dark blue or a black powder insoluble in hydrochloric acid from the compound $TiCl_4.4NH_3$ by heating alone or by reduction with metallic sodium. This material, which he considered to be metallic titanium, is now known to be Ti_3N_4.

Wöhler[4] and Wöhler and Deville[5] in their attempts at producing the metal succeeded in all cases in obtaining the nitrides. Up to this time no analysis of the material produced by the experimenters above mentioned appears to have been made. The confusion which existed in the earlier literature with regard to the pure metal titanium and its nitrides is therefore easily explained.

Nilson and Petersson[6] attempted to prepare metallic titanium by reducing $TiCl_4$ with sodium in an air-tight cylinder of solid steel. The metal was obtained in yellow scales (with frequently a bluish surface color) containing about 95 per cent. of titanium, the chief impurity being the monoxide of titanium.

Then Moissan[7] by reducing titanium dioxide at the extreme temperatures of his electric furnace produced a material containing 5 per cent. of carbon. On reheating this material with titanium dioxide, the amount of carbon was reduced to 2 per cent. and the resulting product was free from nitrogen. This appears to be the nearest approach to metallic titanium which has yet been obtained.

[7] *Compt. rend.*, 120, 290 (1895).

In the following pages each of these methods of preparation is taken up in succession and the results of many attempts to obtain the pure metal from the various compounds of titanium are set out in detail.

Reduction of the Titanifluorides by the Alkali Metals.

In searching in the first instance for materials with which to work it was evident that those substances which were most soluble in water would best suit the purpose: for these materials can be most readily removed on subsequent lixiviation. Among the double fluorides sodium titanifluoride is given by Comey as the most soluble salt and among the simple fluorides of the alkali metals potassium fluoride is deliquescent. The combination of sodium titanifluoride and metallic potassium appeared then the best to use; though, as will be shown, both potassium titanifluoride and barium titanifluoride have been used as a starting material. The sodium titanifluoride was prepared in the following way: Titanium dioxide free from iron was dissolved in hydrofluoric acid. While the liquid was still hot it was filtered from the undissolved residue and almost neutralized by a hot concentrated solution of sodium hydroxide. Sodium titanifluoride was immediately thrown out as a crystalline precipitate, which was easily filtered, then washed with water containing hydrofluoric acid and on drying and bolting was ready for reduction. A sample of K_2TiF_6 prepared in this way was analyzed and found to contain 20.4 per cent. Ti instead of the theoretical 20 per cent. The discrepancy may be due to the presence of some excess of TiF_4 in the double fluoride.

The sodium double fluoride with the potassium necessary for reduction was then placed in an iron cylinder fitted with a lid loosely screwed on. This cylinder was wound with nickel wire which served as a means of heating the cylinder, and was inserted inside a second cylinder of copper which was made perfectly air-tight.

The copper cylinder was evacuated and a current was passed through the nickel wire until the reduction had taken place. This was observed by a slight shift in a manometer attached to the apparatus. When the iron cylinder had cooled it was opened, the excess of potassium was removed by dry alcohol and the whole was then thrown into a large quantity of water. The black powder remaining after several washings was collected on a filter, washed, dried and analyzed. The first material prepared after completely drying in a vacuum caught fire within 30 seconds after being exposed to air. A second material proved to be not pyrophoric in the least degree and could be easily handled in air. An analysis gave from 0.1034 gram on oxidation, 0.1040 gram TiO_2 corresponding to 60.4 per cent. of titanium. A third reduction of Na_2TiF_6 with K on treatment with alcohol and warming with successive small quantities of water gave a material which contained 68.0 per cent. Ti. A fourth experiment carried out *in vacuo* when the conditions for reduction were well ascertained gave a material which contained 73.2 per cent. of titanium.

This represents the best material yet obtained by this method. Three reductions were made on potassium titanifluoride with potassium. The resulting materials contained 60.1, 56.0, 56.1 per cent. of titanium. Barium titanifluoride reduced with potassium gave only 49.5 per cent. of the metal.

It seems to me quite certain that the double fluorides are reduced by the alkalis *in vacuo*, but that in the subsequent removal of the alkaline fluorides, the finely divided metallic titanium is attacked by the water with the ultimate formation of the oxides TiO and TiO_2. In view of the success of a subsequent method of preparing the metal the means for the prevention of this oxidation will not be further discussed.

It remains only to be said that by the methods used by Berzelius, Wöhler and Deville I could not produce a material containing more than 73 per cent. of titanium.

Reduction of Titanium Dioxide by Carbon.

The reduction of titanium dioxide by carbon was next tried as a means of obtaining titanium. To this end the purest lampblack obtainable was taken and fired at a red heat in a gas furnace to remove hydrocarbons and this carbon was then used for the reduction. An intimate mixture of the oxide and carbon was made by grinding and bolting the materials together till the whole appeared a blue homogeneous mass.

The reductions were carried out in an Arsem vacuum furnace, the heat being continued in each experiment until the charge ceased to give off gas. The analyses show the amounts of titanium oxygen and carbon in the resulting product.

EXPERIMENT I, $TiO_2 + 2C$.

Reduction carried out at 5 kw. (1800° C.) in a carbon crucible.
Analysis of product (wt. taken 0 4615 gram):

Ti	0.3656
O	0.0320
C	0.0639

Now since oxygen remains in the mixture it may be safely assumed that the carbon remaining is not in its original free condition but exists in combination with Ti and is not available for reduction. If we assume that it exists as carbide we find:

Ti combined as TiC	0.2556
Ti free or combined with O	0.1100

The ratio of Ti and O considered in atomic proportions is Ti/O = 1.14. The complete analysis of the material is then:

	Per cent.
TiC	69.2
TiO	30.8

The results are tabulated below.

Crucible.	Temp. Degrees.	Per cent. C	Ratio. Ti/O	Per cent. TiC.	Per cent. TiO.
Al_2O_3	1700	10.9	....	54.5	45.5
Carbon	1800	13.8	1.14	69.2	30.8
Carbon	1800	12.7	0 97	63.1	36.9
Carbon	2400	8.7	1.00	43.5	56.5
Carbon	2400	6 6	1 28	26.6	73.4
Tungsten	2100	4 7	....	23 6	76.4
Tungsten	2400	4 6	1.09	24.7	75.3

In general the presence of a crucible made of a substance other than carbon reduces the amount of carbon in the material but the results are largely influenced by difference of temperature during the reduction. The best results were obtained in a tungsten crucible at 2400° where the percentage of carbon remaining in the material sank as low as 4.6 per cent.

But it seems doubtful whether we can prepare metallic titanium by this method. All experiments up to this point have succeeded in giving us only a bluish purple material which contains varying quantities of TiC and TiO.

The Reduction of Titanium Tetrachloride with Sodium.

The best material which Nilson and Petersson[1] prepared by this method contained about 94.73 per cent. of titanium. The material was obtained in yellow scales (frequently with bluish surface color), the chief impurity being considered as oxygen in combination. It is quite probable that the oxygen is combined as TiO in which case the material produced would contain only 78.92 per cent. of metallic titanium.

In repeating the experiment extraordinary care was exercised during and after the reduction of the chloride by sodium to exclude air from the apparatus.

The preparation of titanium chloride was carried out on an extensive scale by the chlorination of approximately pure titanium carbide. The chloride was refluxed in a current of nitrogen to remove chlorine and then repeatedly distilled, the end fractions being continually rejected. The fraction boiling between 136° and 137° was taken and shaken repeatedly with mercury and sodium amalgam. On redistillation a perfectly water white $TiCl_4$ was obtained boiling at constant temperature (136.5° uncorrected).

---

[1] *Loc. cit.*

The first bomb used for the reduction was of 100 cc. capacity accommodating 50 grams of titanium tetrachloride and 25 grams of sodium needed for its reduction. On heating the bomb to a low red heat the reaction took place and on opening it, the titanium was found for the most part as a gray powder, some of it, however, being melted by the heat of the reaction to small metallic beads. By this means however, only 12 grams of metal were obtained in each experiment.

When the progress of the reaction was understood from this experiment on a small scale a larger bomb was constructed of ten times the capacity of the preceding one. In this bomb 500 grams of titanium chloride were successfully reduced by 245 grams of sodium, giving as a theoretical yield 126 grams of titanium. The bomb was constructed of machine steel and was capable of withstanding a total internal pressure of 80,000 pounds. The lid was screwed to the body of the bomb by six stout braces (one inch thick) screwed tightly down with an intervening gasket of soft, annealed copper.

The reaction inside the bomb must be almost instantaneous. The lid is raised a little by the force of the explosion, a slight puff of vapor escapes but the main force of the explosion is already spent and the lid closes air-tight again.

On cooling the bomb and leaching the contents with water, titanium alone remains. Thus in one experiment the weight of $TiCl_4$ used was 470 grams, the titanium content of which is 119 grams. The resultant product contained:

	Grams.
Melted metal	71
Coarse and semimolten powder	31.5
Fine powder	4.5
Total	107

The actual yield was then 90 per cent. The reaction heat had been so great that the greater part of the metal had been more or less perfectly melted during the reaction. The loss of material, amounting to 10 per cent., is accounted for by the fact that some of the titanium is oxidized during the reaction from the presence of oxygen in the sodium used. This introduction of oxygen could not be avoided even when the sodium was carefully peeled before being introduced into the reaction bomb. Again some of the finely divided metal is oxidized by the water during the washing. A flocculent blue ppt. of meta-titanic acid, which rapidly turns white in air, is formed but may be easily removed by decantation from the heavier metal beneath. The slag from the reaction, which should be pure white, is always colored blue or green from the presence of lower titanates of sodium.

This method then is an admirable one for producing titanium in moderately large quantities in a state of purity which has hitherto not been attained.

Analysis of the Material.

A bead of metallic titanium was taken, broken up in three portions and analyzed in the following ways:

1. Dissolved by long boiling in moderately concentrated hydrochloric acid—oxidized with a drop of nitric acid and the titanium precipitated with a slight excess of ammonium hydroxide.

0.1581 gram gave 0.2361 gram TiO_2 equivalent to 0.1579 gram Ti.
Per cent. titanium = 99.9.

2. Dissolved in hydrofluoric acid—neutralized and precipitated with ammonium hydroxide.

0.4365 gram gave 0.7085 gram TiO_2 equivalent to 0.4251 gram Ti.
Per cent. Ti = 97.4.

3. Dissolved in hydrofluoric acid, sulphuric acid added and the solution evaporated to the fuming point, taken up with water and precipitated with ammonium hydroxide.

0.4955 gram gave 0.7954 gram TiO_2 equivalent to 0.4773 gram Ti.
Per cent. Ti = 96.3.

The solution of the metal in hydrofluoric acid always brings about a loss of material due perhaps to the evaporation of titanium fluoride.

4. A fourth method of analysis by the solution of the metal in acid potassium sulphate and subsequent precipitation by boiling the solution gave in the hands of Prof. Mixter[1] 100.2 per cent. of titanium.

No trace of iron or of sodium could be found in the beads of titanium which were melted during the reduction and since two reliable methods of analysis yield results so closely approximating to 100 per cent. There is strong reason to believe that the material thus obtained is pure metallic titanium.

Properties of the Metal.

The metal does not differ in outward appearance from polished steel. It is, however, hard and brittle in the cold. If it be raised to a low red heat it may be readily forged like red hot iron. By this means some of the beads of from 10 to 12 grams in weight have been forged into rods about six inches long.

Unsuccessful attempts have been made to draw the material through a heated draw plate in order to produce wire from it.

The pure metal can be melted only with difficulty. A rod of metal 12 cm. long and 1.8 mm. in diameter burned in air at a temp. of 1200° when a current of 50 amps. was sent through it. The heat of oxidation was sufficient to melt the oxide thus produced. The metal was melted in a lime crucible placed in a vertical carbon tube furnace through which

[1] *Am. J. Sci.*, 27, 393 (1909).

a rapid stream of hydrogen was passed to prevent access of carbon monoxide to the metal. The resulting bead swelled up and became porous in texture resembling titanium carbide. In the Arsem furnace the resulting material was always porous and contained titanium carbide.

A rough determination of the melting point of the material was carried out as follows: The filament of a Gem incandescent lamp was superimposed on a rod of titanium maintained in as perfect a vacuum as could be obtained by a hammering Boltwood pump.

An increasing current was sent through the titanium rod and the temp. of the Gem filament was gradually raised to an equal intensity. It was found that the titanium rod slowly melted and finally broke when the Gem lamp was burning at an efficiency of 3.55 watts per c. p. The melting temperature is therefore between 1800 and 1850° and is certainly not greater than this latter value. Observations, confirming this result, were also made with a Wanner pyrometer.

The specific gravity of the metal is 4.50. It is therefore appreciably lighter than the metal obtained by Moissan (sp. gr. 4.87).

In conclusion it may be said that the metal titanium is not by any means as refractory a substance as former experimenters have been led to believe. Its melting point is comparatively low—being within one hundred degrees of platinum. Further, though brittle in large pieces in the cold yet at a low red heat it shows a remarkable malleability, and very small beads even in the cold may be flattened out with ease without disruption. A method is here given by means of which moderately large quantities of pure titanium may be produced with ease, so that the air of mystery which has so long enshrouded this refractory element will soon be dispelled.

My thanks are due to Dr. W. R. Whitney, of the General Electric Co., for suggestions and generous sympathy during the progress of this research.

NOTE.

The Preparation of Platinum Black.—Of the various methods which have been proposed for the preparation of the finely divided form of platinum known as "platinum black," but two are ordinarily employed, *viz.*, (1) the reduction of a solution of chloroplatinic acid by zinc, and (2) the method of Loew[1] depending on the precipitation of the platinum by means of sodium hydroxide and formaldehyde. In their study of the reducing action of platinum black on nitrates in the presence of formaldehyde, Kastle and Elvove[1] came to the conclusion that platinum black precipitated by means of zinc contains an appreciable amount of the latter metal, the presence of which influences the properties of the black to a greater or less extent, and that this zinc is ordinarily difficult of removal.

---

[1] Loew, *Ber.*, 23, 289 (1890).

It occurred to me that aluminium would be a good metal to use in place of zinc for the production of platinum black, and after a few preliminary experiments, a quantity of black was precipitated by this metal and some of the properties of this preparation investigated.

To prepare this black an aqueous solution of chloroplatinic acid containing 0.5 gram of $PtCl_4$ in 10 cc. is precipitated by the addition of an excess of commercial sheet aluminium. The action is very rapid and generates a great deal of heat. Sufficient strong hydrochloric acid is then added to dissolve any excess of aluminium. When the action is over, the solution presents the uniform black appearance of a strong colloidal solution of platinum, and at the surface of the liquid a platinum mirror is often precipitated on the walls of the container. In this condition, the platinum black will take a long time to settle out, but if the liquid is heated on a steam bath, the black will settle in minute flakes within a couple of hours. The supernatant liquid is usually yellow or greenish, probably from the presence of iron in the aluminium. This liquid is removed by decantation, and the black twice heated for one hour at 100° with fresh quantities of strong hydrochloric acid, which will remove practically all remaining metallic impurities. It is then washed with distilled water by decantation until the wash water gives no test for chlorine with silver nitrate. washed into a small beaker with distilled water, allowed to settle, the excess of water removed by decantation or with a pipette, and the black dried in a vacuum over sulphuric acid, to avoid heating.

The platinum black thus obtained is of a uniform dull black color, and between the fingers reduces to an absolutely impalpable powder. It appears to have a very considerable catalytic power, although quantitative studies of this power were not made at this time.

On analysis, the black thus prepared was found to contain 96.5 per cent. of metallic platinum. In the preliminary experiments, commercial aluminium bronze powder was used as the precipitant, but the black thus obtained was found to be contaminated with a dark brown, amorphous powder of much less specific gravity than the black. This appeared to be a mixture of organic matter and amorphous silicon. With the sheet aluminium the appearance of this contamination was not noted. From the formation of the platinum mirror, it would seem that during the process of precipitation the platinum may actually be in the colloidal state for a brief time. This mirror formation has also been noted in the reduction by formaldehyde (Loew's method), and in the reduction with sodium formate. Magnesium and iron also give very finely divided precipitates of platinum black, but the action does not appear to be so violent as with aluminium, and the blacks obtained are denser and more coherent. That from iron appeared to be badly contaminated with carbon, even though a so-called pure iron wire was used. No analysis of it was made.

---

[1] Kastle and Elvove, *Am. Chem. J.*, 31, 633 (1904).

When heated in the air the following effect upon the weight of the platinum black prepared by precipitation with aluminium was observed: Weight before heating, 0.2661 gram; weight after heating to 300°, 0.2657 gram; weight after heating to redness, 0.2630 gram; or a total loss on heating to redness of about 1.2 per cent., probably representing carbon in the aluminium. Other specimens gave similar figures.

It was also observed that while the platinum black prepared by the use of zinc becomes the gray, "spongy" platinum upon being heated to redness, that precipitated by means of aluminium changes but slightly in color, although it becomes somewhat more coherent.

It therefore appears that by this method one may obtain a quite pure, finely divided platinum black, which will prove useful where this preparation is needed in chemical work.

A RELATION BETWEEN THE CHEMICAL CONSTITUTION AND THE OPTICAL ROTATORY POWER OF THE SUGAR LACTONES.[1]

By C. S. Hudson

Received January 7, 1910.

The Hypothesis.

The numerous sugars are strongly rotatory. On the other hand the alcohols which result from their reduction and the acids which are formed by their oxidation are only feebly rotatory; but the glucosidic compounds of the sugars and the lactones of these acids are as strongly rotatory as the sugars themselves. Thus for example the specific rotations of the two forms of glucose are 109° and 20°, of the methyl glucosides 157° and —32°, of gluconic acid lactone 68°, but the rotation of gluconic acid is only —2°, and sorbitol, which is the alcohol that results from the reduction of glucose, shows no rotation. Is there any other property of these substances which varies in the same manner as the rotatory power?

The constitutional chemical formulas now in use for these compounds have been chosen step by step to express their chemical reactivities;

---

[1] Read at the Boston meeting of the American Chemical Society, Dec., 1909.

and it is now generally agreed that the sugars, the glucosides and the lactones possess a lactonic ring, but that this is absent from the structure of the alcohols and acids. Here then is a property—the chemical constitution—which runs exactly parallel with the physical property of optical rotation, in the case of the sugar glucose. Does the same parallelism hold for the other sugars?

To answer this question reference may be made to Table I, which gives the specific rotations of the principal aldose sugars, and their glucosidic, lactonic, acidic, and alcoholic derivatives, so far as they are known; the numerical values are in all cases quoted from the literature.

TABLE I.—SPECIFIC ROTATIONS OF ALDOSE SUGAR DERIVATIVES.

Sugar.		Glucosidic compound		Lactone.		Acid.	Alcohol.	
d-Glucose	α 109° β 52°	Methyl	α 157° β −32°	Gluconic	68°	−2°	Sorbitol	0
d-Galactose	α 140° β 53°	Methyl	α 196° β 0°	Galactonic	−72°	−11°	Dulcitol	0
l-Arabinose	α 76° β 184°	Benzyl	215°	Arabonic	−74°	−8°	Arabitol	0
d-Mannose	α 76° β −14°	Methyl	−79°	Mannonic	54°	?	Mannitol	0
d-Xylose	α 100° β −8°	Methyl	α 152° β −66°	Xylonic	83°	−7°	Xylitol	0
l-Rhamnose	α <−7° β > 31°	Methyl	−62°	Rhamnonic	−35°	−8°	Rhamnitol	11°
l-Ribose	?	?		Ribonic	−18°	?	Adonitol	0
d-Mannoheptose	85°	?		Mannoheptonic	−74°	?	Mannoheptitol	−1°
Rhodeose	86°	Ethyl	30°	Rhodeonic	−76°	?	?	
d-Talose	?	?		Talonic	—(strong)	?	Talitol	0.2°
d-Gulose	?	?		Gulonic	−55°	?	Sorbitol	0
α-Galaheptose	?	?		α-Galaheptonic	−52°	?	α-Galaheptitol	0
β-Galaheptose	−22°	?		β-Galaheptonic	?	?	?	
α-Gluco-octose	−51°	?		α-Gluco-octonic	46	?	α-Gluco-octitol	2°
d-Mannononose	50°	?		d-Mannonononic	−41°	?	?	
d-Gala-octose	−40°	?		d-Gala-octonic	64°	?	?	

The above data from the literature show that the sugars, the glucosidic compounds and the lactones, all of which contain the lactonic ring, have strong rotatory powers. There are three apparent exceptions, β-methyl galactoside, β-xylose and α-rhamnose, but for each of these the corresponding α or β isomer is strongly rotatory, proving that the slight rotations of the three compounds are due to internal compensations, and that they contain strongly active carbon atoms. On the other hand the alcohols and acids are of feeble rotatory powers, which are in general not comparable with the strong rotations of the sugars, glucosidic compounds and lactones. There is thus satisfactory proof that the lactonic ring structure causes a strong rotatory power.

The rotations of the alcohols and acids recorded are so small in comparison with those of the lactones that the rotations of the latter may be assumed to be due, as a first approximation, entirely to the lactonic ring. There are two possible stereo structures for the lactonic ring, namely  and , which are mirror images (with the mirror placed horizontally).[1] If the rotation of the lactone is due entirely to this ring the position of the ring must determine the sign of the rotation of the lactone. The position of the ring is determined by the position which the OH group had on the γ-carbon atom before the ring was formed. These ideas thus lead to the following hypothesis: *Lactones of dextrorotation have the lactonic ring on one side of the structure, lactones of levorotation have it on the other and the position of the ring shows the former position of the OH group on the γ-carbon atom.*

Test of the Hypothesis.

This hypothesis will now be tested. In Table II there are collected the structural formulas and specific rotations of twenty-four lactones of the monobasic sugar acids, including every such lactone for which the structure and specific rotation have been determined. The first column gives the name and the second the stereo configuration of the lactone, the discovery of which is due in all cases to the immortal researches of Emil Fischer. In the third column is the statement, for convenience, of the position of the lactonic ring, whether "above" or "below" the chain, and in column four are the specific rotations of the lactones, which are quoted from the references given in the foot-notes. In most cases they were measured by Emil Fischer or his students.

TABLE II.—PARALLELISM BETWEEN THE SIGN OF THE ROTATION AND THE CONFIGURATION OF THE SUGAR LACTONES.

Lactone.	Fischer's configuration.	Ring position	Specific rotation.
l-Arabonic	 $\mathrm{CH_2OH.C\ .\ C\ .\ C\ .\ CO}$	Above	—74°[2]
l-Ribonic	 $\mathrm{CH_2OH.C\ .\ C\ .\ C\ .\ CO}$	Above	—18°[3]

---

The table shows that among these twenty-four sugar lactones (which include all the known substances upon which there is sufficient data known to test the hypothesis) there is not a single exception to the theory; all the lactones which have the ring "above" the chain are levorotatory and all having it "below" the chain are dextrorotatory.

Application of the Theory to Determine the Constitution of the Sugars.

As this relation between the stereo position of the lactonic ring and the sign of the rotation of the lactone is well founded it may be used in determining the constitution of the sugars. For some of the sugars such a determination is only a tracing backward of the steps of the above experimental proof of the hypothesis, but for certain others (*e. g.*, rhamnose) this method gives entirely new data on the constitution, as will be shown. In determining the constitutions of the sugars Emil Fischer has used most ingeniously a mass of chemical data of various kinds, nearly all of which he worked out in his own laboratory; in what follows it will be shown that the constitutions of the monose aldehyde sugars can be independently determined from two kinds of experimental data, (1) a knowledge of the sugars which result from the cyanide synthesis or its reverse, and (2) a knowledge of the signs of the rotations of the lactones of the monobasic sugar acids. This second kind of data cannot be obtained for the ketone sugars because they do not yield acids and lactones, and their structure cannot be found by this method alone.

---

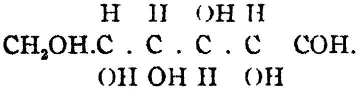
[1] E. Fischer, *Ann.*, **270**, 94 (1892)

[2] *Ibid.*, **270**, 101 (1892).

[3] *Ibid.*, **288**, 149 (1895).

[4] *Ibid.*, **270**, 103 (1892).

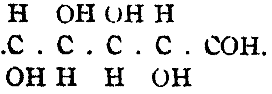
The Stereo Configuration of d-Glucose.—The cyanide synthesis or its reverse has shown the steps of the following series: *d*-erythrose ⟶ *d*-arabinose ⟶ *d*-glucose ⟶ *d*-glucoheptose ⟶ *d*-gluco-octose. The specific rotations of the lactones of the monobasic acids derived from these sugars are (see Table II), *d*-arabonic +74°, *d*-gluconic +68°, *d*-glucoheptonic —68°, *d*-gluco-octonic +46°. Writing the carbon chain of the octose $CH_2OH.\underset{(1)}{C}.\underset{(2)}{C}.\underset{(3)}{C}.\underset{(4)}{C}.\underset{(5)}{C}.\underset{(6)}{C}.\underset{(7)}{C}$, it is first noticed that as its lactone rotates positive (+46) its ring is to be considered below the chain and joining atom 7 to its γ-carbon 4. This shows that the H atom on 4 is above the chain. Passing next to the heptose, since its lactone rotates negative (—68°) the H atom on the new γ-carbon 3 by the same reasoning is below the chain. Similarly the signs of the rotations of the other two lactones show that the H atom is above 2 and above 1. This determines the stereo constitution of the carbons 1, 2, 3, and 4, and as these are all the asymmetric carbons which occur in the aldehyde formula of glucose, this may be written



$$CH_2OH.\overset{H}{\underset{OH}{C}}\ .\ \overset{H}{\underset{OH}{C}}\ .\ \overset{OH}{\underset{H}{C}}\ .\ \overset{H}{\underset{OH}{C}}\ \ COH.$$

This formula is identical with the one which Emil Fischer has chosen from chemical data alone. The steps of the above proof of the structure of *d*-glucose give also the structures of *d*-arabinose and *d*-erythrose.

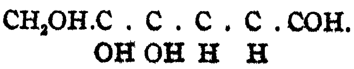
The Stereo Configuration of d-Galactose.—The cyanide synthesis or its reverse has shown the following series: *d*-lyxose ⟶ *d*-galactose ⟶ *d*-galaheptose ⟶ *d*-galaoctose, and the rotations of the lactones of the corresponding monobasic acids have been found to be (Table II) *d*-lyxonic +82°, *d*-galactonic —78°, *d*-galaheptonic −52°, *d*-galaoctonic +64°. By the same reasoning as given above these rotations show that in the stereo formula of galactose the H atom is above carbons 1 and 4 and below 2 and 3, giving



$$CH_2OH.\overset{H}{\underset{OH}{C}}\ .\ \overset{OH}{\underset{H}{C}}\ .\ \overset{OH}{\underset{H}{C}}\ .\ \overset{H}{\underset{OH}{C}}\ .\ COH.$$

This formula is identical with the one which Fischer has chosen for galactose. The stereo configuration of *d*-lyxose follows from that of *d*-galactose.

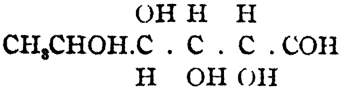
The Stereo Configuration of d-Mannose.—The cyanide reaction has shown the following series: *d*-arabinose ⟶ *d*-mannose ⟶ *d*-mannoheptose ⟶ *d*-manno-octose, and the rotations of the lactones of the corresponding monobasic acids have been found to be (Table II) *d*-arabonic +74°, *d*-mannonic +54°, *d*-mannoheptonic —74°, *d*-manno-octonic —44°. In the configuration of mannose therefore the H atom is below 3 and 4 and above 1 and 2, giving



$$CH_2OH.\overset{H}{\underset{OH}{C}}\ .\ \overset{H}{\underset{OH}{C}}\ .\ \overset{OH}{\underset{H}{C}}\ .\ \overset{OH}{\underset{H}{C}}\ .COH.$$

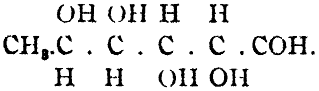
This is also identical with the structure which Fischer has established for mannose.

The Stereo Configuration of Rhamnose.—This methyl pentose sugar has been shown by Fischer to have the stereo configuration



$CH_3CHOH.\underset{H}{\overset{OH}{C}}\,.\,\underset{OH}{\overset{H}{C}}\,.\,\underset{OH}{\overset{H}{C}}\,.COH$

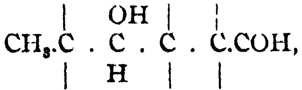
but he was unable to obtain any data which would establish the stereo structure of the first asymmetric group CH_3CHOH. This physico-chemical method for establishing the structure of the sugars can be applied in this case where the usual strictly chemical methods fail. Writing the carbon chain for rhamnose $CH_3.\underset{(1)}{C}.\underset{(2)}{C}.\underset{(3)}{C}.\underset{(4)}{C}.\underset{(5)}{C}$, and referring to the following cyanide syntheses, methyl tetrose ⟶ rhamnose ⟶ rhamnohexose ⟶ rhamnoheptose, the specific rotations of the corresponding lactones having been found to be methyl tetronic —47°,[1] rhamnonic —35°, rhamnohexonic +84°, and rhamnoheptonic +56°, it is seen that the hydrogen atom is to be placed above carbons 3 and 4 and below 1 and 2, yielding the following configuration for rhamnose,



$CH_3.\underset{H}{\overset{OH}{C}}\,.\,\underset{H}{\overset{OH}{C}}\,.\,\underset{OH}{\overset{H}{C}}\,.\,\underset{OH}{\overset{H}{C}}\,.COH$.

This agrees with Fischer's structure for the atoms 2, 3, and 4, and it also shows the configuration of the atom 1 which has been in doubt. Rhamnose is thus a reduction product from *l*-mannose. It is interesting to note that Winther[2] has previously selected this configuration for the first carbon, basing his selection upon the fact that Tate's bacillus attacks rhamnose.

Partial Stereo Configurations of Rhodeose and Fucose.—The methyl pentose rhodeose yields a lactone with the specific rotation —76°,[3] consequently its structure can be partially determined from the above principles to be



$CH_3.\underset{|}{\overset{|}{C}}\,.\,\underset{H}{\overset{OH}{C}}\,.\,\underset{|}{\overset{|}{C}}\,.\,\underset{|}{\overset{|}{C}}.COH$,

and it follows that its antipode, fucose, is the mirror image of this.

Proof of the Position of the Lactonic Ring.

The foregoing relations furnish a proof of a view which organic chemists have been led to adopt by a large number of chemical facts, namely, that the formation of lactones involves the γ-carbon atom preferably to any other. The parallel relation between the position of the lactonic ring and the sign of the rotation of the lactone is based on the assumption that the ring is formed on the γ-carbon atom; if it were considered as formed on any other atom whatsoever the parallelism would no longer hold even approximately; thus, referring back to Table II, if the ring is supposed to form on the α-atom, there are then seven cases of agreement with the hypothesis of parallelism, eight disagreements and nine remaining doubtful. If the ring forms on the β-carbon there are then ten cases of agreement and ten of disagreement and four in doubt. If the ring forms on the δ-carbon there result six agreements, twelve disagreements and six doubtful. But it has been seen that if the ring forms on the γ-carbon there are twenty-four agreements, no disagreements and none in doubt. As the chances that an event which can happen in two equally probable ways will happen in exactly the same way twenty-four times out of twenty-four trials is only one in seventeen million it seems certain that the lactonic ring in these monobasic sugar lactones forms on the γ-carbon atom.

CHEMICAL EXAMINATION OF PUMPKIN SEED.

By Frederick B. Power and Arthur H Salway

Received January 13, 1910.

The seeds of the common pumpkin (*Cucurbita pepo*, Linné) have been recognized for several decades by the United States Pharmacopoeia under the title of *Pepo*, and are regarded as an efficient and harmless taenifuge. This property appears to have been generally attributed to the fatty oil contained in the seed, which is stated to have been used with success in repeated half-ounce doses.[1] On the other hand, Heckel[2] found that the membrane surrounding the embryo is capable of expelling tapeworms, and as the membrane contains a resin, he believed this to be the active constituent There is, however, no indication that Heckel had in any way confirmed this supposition by the separate administration of the resin. A more definite observation regarding the activity of the resin appears to have been made by Wolff, since it is recorded[3] that he found this efficient as a taenifuge in doses of 15 grams, whereas the fatty oil, when pure and free from resin, was inert. Ordinarily, however, the remedy is employed in the form of the kernels of the fresh seed, suitably prepared, in doses ranging from 30 to 200 grams.

No complete chemical examination has hitherto been made of pumpkin seeds, and the constituents of their fatty oil have been only imperfectly known. The results of an investigation by Kopylow,[4] in 1876, showed that previous statements respecting the presence of an alkaloid or glucoside in these seeds could not be confirmed, but that they contained, besides fatty oil, some sugar and a soft resin. The expressed oil was stated to consist of the glycerides of palmitic, myristic, and oleic acids, while the oil extracted from the press-cake by means of ether also contained these acids in a free state. Lewkowitsch[1] describes pumpkin seed oil, and records its physical and chemical constants, as also some of the constants of the mixed fatty acids obtained from the oil, but makes no statement concerning its composition.

In view of the medicinal use of pumpkin seeds, and the deficiency of knowledge respecting their constituents, it seemed desirable to subject them to a complete examination. It was also thought possible that thereby, in conjunction with physiological tests, some further and more definite information might be obtained as to the character of the constituent upon which their reputed action as a taenifuge depends. The results of the present investigation, together with the conclusions drawn therefrom, are summarized at the end of this paper.

EXPERIMENTAL.

The material employed was obtained from the United States, and consisted of fresh pumpkin seeds, which corresponded in all respects to the description given of them in the United States Pharmacopoeia.

A portion of the crushed seed was first tested for the presence of an alkaloid by means of Prollius' fluid, but with a negative result.

For the purpose of a complete examination, 22.5 kilograms of the seed were crushed and the shells separated as completely as possible from the kernels. The shells amounted to 4.68 kilograms, thus corresponding to 20.8 per cent. of the weight of the seed. The ground kernels were then subjected to strong hydraulic pressure, when 4350 grams of fatty oil were obtained, corresponding to 19.3 per cent. of the weight of the entire seed. The so-called "press-cake" remaining after the removal of the oil amounted to 12.7 kilograms. These operations connected with the expression of the oil were carefully conducted for us by Messrs. Stafford, Allen & Sons, of London, to whom our thanks are due.

A portion of the entire seed, when ground and extracted in a Soxhlet, apparatus with light petroleum (b. p. 30–45°), yielded 34.3 per cent. of fatty oil.

I. Examination of the Expressed Oil.

The expressed oil of pumpkin seed, as obtained by us, when viewed in layers of moderate thickness, has a cherry-red color, and possesses a marked fluorescence, whereas in thin layers it appears greenish yellow. It is optically inactive. The constants of the oil were determined with the following results:

---

[1] "Chemical Technology and Analysis of Oils, Fats and Waxes," 3rd Edit., Vol. II, p. 509.

	Expressed oil.	Oil extracted by petroleum.
Specific gravity 20°/20°	0.9220	0.9212
Acid value	3.4	3.5
Saponification value	189.4	189.0
Iodine value	119.7	119.6

For a complete chemical examination of the oil, 250 grams of it were employed. It was first subjected to distillation with steam. The distillate contained no volatile oil and had only a very slight acid reaction, which appeared to be due to traces of acetic acid.

Hydrolysis of the Oil.

The oil which had been subjected to distillation with steam, as above described, was separated from the water, the latter then extracted with ether to recover a small amount of suspended oil, and, after adding this to the main portion, the whole was hydrolyzed by heating with an alcoholic solution of 70 grams of potassium hydroxide. The greater portion of the alcohol was then removed, water added, and the alkaline liquid repeatedly extracted with ether. The ethereal liquids were united, washed with a little water, dried with anhydrous sodium sulphate, and the ether removed, when about 1 gram of a yellow solid was obtained. On fractionally crystallizing the latter from ethyl acetate, the least soluble fraction was obtained in colorless needles, melting at 162–163°. After drying at 110° it was analyzed:

0.0698 gave 0.2139 CO_2 and 0.0749 H_2O. C = 83.6; H = 11.9.
$C_{27}H_{46}O$ requires C = 83 9; H = 11.9 per cent.

The analysis of this substance, together with the characteristic color reactions yielded by it, establishes its identity as a phytosterol.

The mother liquors from this phytosterol yielded crystalline deposits melting considerably lower than the latter, and the presence of another substance of this class, having an initial melting point of 140°, was indicated. On account of the very small amount of material it was, however, not possible to isolate the more soluble compound in a state of purity.

The Fatty Acids.

The alkaline, aqueous solution of potassium salts, which had been extracted with ether, as above described, was acidified with sulphuric acid and the liberated fatty acids taken up by ether. The ethereal solution was washed, dried, and the solvent removed, when 225 grams of total fatty acids were obtained. The constants of the mixed acids were determined in a portion from which the last traces of ether had been removed by heating for some time at 100° under diminished pressure, and were then as follows: M. p. (complete fusion), 31°; *d* 50°/50° = 0.8886; neutralization value, 199; iodine value, 123.5. Optically inactive. A determination of the acetyl value indicated the absence of hydroxy acids. No volatile acids could be detected, either in the total mixture of acids or in the aqueous liquid from which they had been removed by means of ether.

The mixed fatty acids, which consisted of a liquid and a solid portion, were first partially separated by filtration, with the aid of a pump. The solid portion, amounting to 30 grams, was fractionally crystallized from alcohol, and the fractions representing the two extremes of solubility, which melted at 57–58° and 50–54°, respectively, were analyzed.

Fraction Melting at 57–58°.—0.1290 gave 0 3561 CO_2 and 0.1463 H_2O. C = 75.3; H = 12.6.

0.1714 gave 0 4727 CO_2 and 0 1961 H_2O. C = 75.2; H = 12.7.

0.2306 neutralized 8.55 cc. 0.1 *N* KOH. Neutralization value = 208

Fraction Melting at 50–54°.—0.1800 gave 0.5003 CO_2 and 0.2048 H_2O. C = 75.8; H = 12 6.

$C_{16}H_{32}O_2$ requires C = 75 0; H = 12.5 per cent.

$C_{18}H_{30}O_2$ requires C = 76.1; H = 12.7 per cent.

These results indicated that both of the above fractions consisted of mixtures of palmitic and stearic acids. As their separation could not be effected by fractional crystallization, this was accomplished by fractionally precipitating a hot alcoholic solution of the acids with concentrated, aqueous barium acetate. Thus the fraction melting at 57–58° was converted into five fractions of barium salt, which, on treatment with hydrochloric acid, yielded acids melting at 66–67°, 64–65°, 62–63°, 59–60°, and 55–56°, respectively. Those of these fractions were analyzed:

Fraction Melting at 66–67°.—0 1247 gave 0 3474 CO_2 and 0.1440 H_2O. C = 76.0; H = 12.9.

$C_{18}H_{36}O_2$ requires C = 76.1; H = 12.7 per cent.

Fraction Melting at 59–60°.—0.1194 gave 0.3270 CO_2 and 0.1338 H_2O. C = 74.7; H = 12.5.

$C_{16}H_{32}O_2$ requires C = 75.0; H = 12.5 per cent.

Fraction Melting at 55–56°.—0.1030 gave 0 2858 CO_2 and 0.1159 H_2O. C = 75.7; H = 12.5.

This fraction was somewhat impure, and the fact that its carbon content is higher than the next preceding one, may be attributed to the presence of a little of the unsaturated acid contained in the oil.

The above results have thus afforded conclusive evidence that the solid acids consisted of a mixture of palmitic and stearic acids, the former predominating. There is, therefore, no indication of the presence of myristic acid, which has been stated[1] to be a constituent of pumpkin seed oil.

The liquid portion of the total fatty acids was neutralized with an alcoholic solution of potassium hydroxide, and subsequently an alcoholic solution of lead acetate added. The precipitated lead salt was thoroughly washed with water by decantation, and then digested with ether on a water bath. The ethereal solution, containing the lead salts of the unsaturated acids, was treated with dilute hydrochloric acid, filtered from the lead chloride, washed with water, and the ether removed. The unsaturated acids thus obtained from 250 grams of the fatty oil amounted to 140 grams, and possessed the following constants: B. p. 225–230°/12 mm.; *d* 20°/20° = 0.9009; acid value 195.3; iodine value 144.3. The product was analyzed with the following result:

---

[1] *Loc. cit.*

0.1354 gave 0.3807 CO_2 and 0.1416 H_2O. C = 76.7; H = 11.6.
$C_{18}H_{34}O_2$ requires C = 76.6; H = 21.1 per cent. Iodine value = 90.1.
$C_{18}H_{32}O_2$ requires C = 77.1; H = 11.4 per cent. Iodine value = 181.4.

It was evident from these results that the unsaturated acids also consisted of a mixture, and, in order to ascertain more definitely the nature of their constituents, a portion (36 grams) was oxidized, in alkaline solution, with an equal amount of potassium permanganate. A one per cent. solution of the latter was added gradually at the ordinary temperature, with constant stirring, and at the end of the operation sulphur dioxide was passed into the mixture until all the manganese oxide had dissolved. A pure white precipitate was thus obtained, which was separated by filtration, and digested with large quantities of ether at the ordinary temperature. The ethereal solution, after the removal of the solvent, yielded a product which, when crystallized from alcohol, separated in pearly leaflets, melting at 129–130°:

0.1240 gave 0.3093 CO_2 and 0.1276 H_2O. C = 68.0; H = 11.4.
$C_{18}H_{36}O_4$ requires C = 68.4; H = 11.4 per cent.

This product was evidently dihydroxystearic acid, and its formation proved the presence of oleic acid in the oil.

The portion of the oxidation product remaining undissolved by the above-described treatment with ether was repeatedly boiled with large quantities of water and the liquids filtered. The filtrates yielded crystalline deposits melting at about 155°. On recrystallizing these from alcohol, small leaflets were obtained which melted at 157–159°, and this melting point was not raised by fractional crystallization from either alcohol or acetic acid:

0.1470 gave 0.3314 CO_2 and 0.1365 H_2O. C = 61.5; H = 10.3.
$C_{18}H_{36}O_6$ requires C = 62.1; H = 10.3 per cent.

This substance is evidently a tetrahydroxystearic acid (sativic acid), although its melting point is lower than that usually assigned to the latter, namely 173°. It has been noted, however, by several observers that products agreeing in composition and character with tetrahydroxystearic acid possessed melting points varying from 152 to 165°, and it is therefore possible that these represent isomeric acids of the formula $C_{18}H_{36}O_6$.[1]

---

[1] Compare Lewkowitsch, "Chemical Technology and Analysis of Oils, Fats, and Waxes," 2nd Edit., Vol. I, p. 126, and *J. Chem. Soc.*, 87, 899 (1905).

The isolation of tetrahydroxystearic acid as one of the products of oxidation of the unsaturated acids of pumpkin seed oil is evidence of the presence in the latter of linoleic acid. As no hexahydroxystearic acid (linusic acid) could be isolated from the products of oxidation, it may be concluded that linolenic acid is not a constituent of the oil.

The portion of the precipitated lead salt which remained undissolved by the above-described treatment with ether was examined as follows: The acid was recovered and dissolved in alcohol, when by the addition of successive portions of barium acetate five fractions of barium salt were obtained The corresponding fractions of acid from these salts melted at the following temperatures: (I) 53-54°; (II) 53-54°; (III) 53-54°; (IV) 54-56°, (V) oily. After recrystallization, the melting points were as follows: (I) 56-58°; (II) 55-56°; (III) 54-55°, (IV) 57-59°. The acid values of these fractions corresponded to the following molecular weights: (I) 270; (II) 265; (III) 264; (IV) 260. The molecular weights of palmitic and stearic acids are 256 and 284 respectively. It was thus ascertained that the solid acids contained in that portion of the precipitated lead salt which was not dissolved by ether were the same as those initially separated from the total fatty acids, and consisted of a mixture of palmitic and stearic acids.

II. Examination of the Press-cake.

The so-called "press-cake," resulting from the expression of 22 5 kilograms of pumpkin seeds, deprived as completely as possible of the shells, amounted, as previously noted, to 12 7 kilograms. This material was completely extracted with hot alcohol, when, after the removal of the greater portion of the alcohol, a thin, dark-colored, oily extract was obtained, amounting to 2565 grams. The extract was brought into a flask with water and subjected to distillation with steam, but yielded no volatile product. The contents of the distillation flask separated, on cooling, into an upper layer of fatty oil (*A*) and a lower aqueous liquid (*B*), the latter containing some resin (*C*).

The Fatty Oil (A).

After separating the fatty oil as completely as possible from the aqueous liquid, the latter was extracted with light petroleum to remove a small amount of suspended oil. The petroleum liquids were then added to the main portion of oil, the whole filtered to remove suspended resin, washed with a little water, dried, and the petroleum removed. A quantity (1950 grams) of a dark green, fatty oil was thus obtained, which possessed the following constants: $d\ 20°/20° = 0.9230$; saponification value, 193.4; iodine value, 115.4. These figures are observed to be in close agreement with those afforded by the expressed oil, the complete investigation of which has already been described. It was therefore evident that this product from the press-cake merely represented that portion of the fatty oil of pumpkin seed which had not been removed by expression.

The Aqueous Liquid (B).

As the resin (*C*) contained in the aqueous liquid (*B*) was in too fine a state of division to admit of its separation by filtration, this was effected by decantation, and it was subsequently well washed with water in the same manner. The aqueous liquid (*B*) then possessed a dark brown color, and when heated with a solution of sodium hydroxide developed ammonia. It yielded a precipitate with mercuric-potassium iodide and with iodine solution, but this behavior was evidently due to protein compounds and not to the presence of an alkaloid, since a preliminary test of the powdered seed for substances of this class by means of Prollius' fluid had given a perfectly negative result.

Isolation of Salicylic Acid.

The aqueous liquid was repeatedly extracted with ether, the ethereal liquid being washed, dried, and the solvent removed. About 1 gram of a brown, viscid mass was thus obtained, which gave, with ferric chloride a deep violet coloration. In order to purify the product it was warmed with aqueous sodium carbonate and animal charcoal, but the filtered liquid, on acidification, yielded a precipitate which could not be directly crystallized. On digesting the latter, however, with a large volume of light petroleum, filtering from the resinous matter, and removing the solvent, a very small quantity of colorless needles was obtained, which melted at 150–153°. The substance was soluble in sodium carbonate with evolution of carbon dioxide, gave a violet coloration with ferric chloride, and when heated with methyl alcohol in the presence of sulphuric acid developed the characteristic odor of methyl salicylate. Although the amount of this substance was not sufficient for an analysis, its identity as salicylic acid could be considered definitely established.

Treatment with Basic Lead Acetate.

The aqueous liquid, after extraction with ether as above described, was treated with basic lead acetate, which produced a voluminous, yellowish brown precipitate. This was collected on a filter, thoroughly washed with water, then suspended in water, and decomposed by hydrogen sulphide. On filtering the mixture a yellowish red liquid was obtained, which gave only a slight brown coloration with ferric chloride. The liquid was concentrated under diminished pressure, and, as it gave nothing crystalline on standing, was finally mixed with purified sawdust, and the dried mixture successively extracted in a Soxhlet apparatus with ether, ethyl acetate, and alcohol. These solvents, however, did not effect the separation of any crystalline substance.

The filtrate from the basic lead acetate precipitate was treated with hydrogen sulphide for the removal of the excess of lead, filtered, and this filtrate concentrated under diminished pressure. A reddish brown sirupy liquid was thus obtained, which contained a large amount of sugar, since it readily yielded *d*-phenylglucosazone, melting at 215°. The liquid deposited nothing crystalline, even on long standing, and a portion, when dried in purified sawdust and extracted successively with ether, ethyl acetate, and alcohol, likewise yielded nothing of a crystalline nature.

Treatment of the Purified Aqueous Liquid with Dilute Sulphuric Acid.

A portion of the aqueous liquid which had been purified by treatment with basic lead acetate, as above described, was heated for some time in a reflux apparatus with such an amount of sulphuric acid that the latter represented about 5 per cent. by weight of the mixture. On subsequently passing steam through the liquid, the distillate was found to contain formic and acetic acids, but no oily drops. The aqueous, acid liquid remaining in the distillation flask contained a comparatively large quantity of resin. This was collected and well washed with water, but it was quite insoluble in the usual organic solvents, and possessed no further interest. After the separation of the resin, the aqueous liquid, which had a dark brown color, was extracted many times with ether. The combined ethereal liquids were washed, dried, and the solvent removed, when about 3 grams of a yellowish brown oil were obtained, which was fractionally distilled under the ordinary pressure. A small fraction was collected at 100–120°, which contained formic and acetic acids, but the larger portion distilled between 230 and 240°. On redistilling the latter, it passed over between 240 and 260°. This oil possessed a light yellow color, was freely soluble in water, and gave a precipitate with phenylhydrazine acetate. It was, furthermore, soluble in sodium carbonate with evolution of carbon dioxide and yielded a crystalline silver salt. The latter was precipitated in two fractions by the successive addition of silver nitrate to a solution of the sodium salt, and these fractions, after drying in a vacuum over sulphuric acid, were analyzed:

I. 0.0973 of salt gave on ignition, 0.0462 Ag. Ag = 47.5.
II. 0.5404 of salt gave on ignition, 0.2628 Ag. Ag = 48.6.
$C_5H_7O_3Ag$ requires Ag = 48.4 per cent.

These results established the identity of the above-described substance as levulinic acid. Its formation may be attributed to the action of the sulphuric acid on the sugar contained in the aqueous liquid.

The aqueous liquid from which the levulinic acid had been extracted was next treated with just sufficient baryta to remove the sulphuric acid, then filtered, and the filtrate concentrated. A dark brown sirup was thus obtained, which deposited nothing crystalline on standing.

It will be seen from the above results that the purified aqueous liquid, on heating with sulphuric acid, yielded no product which would indicate the presence in it of a glucoside.

The Resin (C).

The resinous material from the "press-cake" amounted to 110 grams, and to this was added a small quantity (10 grams) of resin obtained from the shells of the seed. For the examination of this resinous material it was digested with hot alcohol, then mixed with purified sawdust, and the thoroughly dried mixture extracted successively in a Soxhlet apparatus with various solvents, when the following amounts of extract, dried at 100°, were obtained:

Petroleum (b. p. 30–45°)	extracted	75.0	grams	= 62.5	per cent.
Ether	"	5 0	"	= 4.2	"
Chloroform	"	6.0	"	= 5.0	"
Ethyl acetate	"	2.2	"	= 1.8	"
Alcohol	"	16 0	"	= 13.3	"
Total,		104.2	"	= 86.8	"

By this process of extraction a portion of the resin had evidently been rendered insoluble.

Petroleum Extract of the Resin.

This was a soft, black mass. It was heated in a reflux apparatus with an excess of an alcoholic solution of potassium hydroxide, the greater portion of the alcohol then removed, water added, and the alkaline mixture extracted with ether. The ethereal liquids were washed, dried, and the solvent removed, when about 1 gram of a light yellow solid was obtained. This was crystallized a few times from a mixture of ethyl acetate and alcohol, when it finally separated in thin plates, melting at 157–159°. It was a phytosterol, and apparently identical with that previously isolated from the expressed oil of the seed.

Isolation of a New Monocarboxylic Acid, $C_{25}H_{51}O.CO_2H$.

The alkaline, aqueous liquid, from which the above-mentioned phytosterol had been separated, contained an insoluble potassium salt in suspension. This was removed by filtration and separately examined. For this purpose it was heated for some time with dilute sulphuric acid in the presence of chloroform, when a solution of the corresponding free acid in chloroform was obtained. This solution was washed, dried, and the solvent removed, when it yielded about 0.5 gram of a solid, wax-like substance. The latter was twice crystallized from alcohol, when it melted at 99°.

0.0986 gave 0.2728 CO_2 and 0 1138 H_2O. C = 75.5; H = 12.8.
0.0777 neutralized 1.65 cc. 0.1 *N* KOH Neutralization value = 119.1.
$C_{26}H_{52}O_3$ requires C = 75.7; H = 12 6 per cent. Neutralization value = 136 1.

The composition of this substance would thus appear to be represented by the formula $C_{26}H_{52}O_3$, which is that of a hydroxycerotic acid. Two hydroxycerotic acids have hitherto been recorded, one of which was obtained synthetically and is stated to melt at 86 5°,[1] while the other, calculated for the formula $C_{27}H_{54}O_3$, was isolated from coca leaves, and is stated to melt at 82°.[2] As the above-described acid melts at a considerably higher temperature than either of the acids noted, it is apparently identical with neither of them, and may possibly represent one of the numerous isomerides.

The acid, $C_{26}H_{52}O_3$, is very sparingly soluble in light petroleum and in cold alcohol, but is moderately soluble in hot alcohol, and dissolves more readily in ethyl acetate. When heated with ethyl alcohol in the presence of concentrated sulphuric acid, it yielded an *ethyl ester*, which melted at 61°. An attempt to obtain an acetyl derivative of the acid was not successful.

The *alkaline, aqueous liquid* from which the insoluble potassium salt had been removed, as above described, was acidified with sulphuric acid and distilled with steam, but no volatile acid was found in the distillate. The contents of the distillation flask were then extracted with ether, the ethereal liquid being filtered to remove some suspended resin, washed, dried, and the solvent removed. A quantity of dark colored, solid fatty acid was thus obtained which, when distilled under diminished pressure, passed over almost entirely between 228 and 233°/15 mm., only a small amount of non-volatile resin remaining behind. The distillate was crystallized from acetic acid, when a product was obtained which melted at 54°.

0.2224 neutralized 8 05 cc. 0 1 *N* KOH. Neutralization value = 203.1.
$C_{16}H_{32}O_2$ requires a neutralization value of 219.1
$C_{18}H_{36}O_2$ requires a neutralization value of 197.5.

This product evidently consisted of a mixture of palmitic and stearic acids.

The mother-liquors remaining from the crystallization of the above product were found to contain some unsaturated acid. The acids contained in the mixture were therefore evidently the same as those previously identified by us in the expressed oil of pumpkin seed.

Ether Extract of the Resin.

This was a black, soft solid, amounting to only 5 grams. It was redissolved in ether, the ethereal solution being then extracted with aqueous sodium carbonate, and subsequently with a 10 per cent. solution of sodium hydroxide. The sodium carbonate extract had a dark brown color and contained some insoluble sodium salt in suspension. The whole was acidified with dilute sulphuric acid, and extracted with ether, the ethereal liquid being washed, dried, and the solvent removed. A dark brown solid was thus obtained, which was dissolved in alcohol, and the solution decolorized by animal charcoal. On concentrating the liquid a very small amount of a colorless substance was deposited, which melted at 98–99° and was identical with the acid $C_{20}H_{32}O_3$, which had previously been isolated from the petroleum extract of the resin. The subsequent extraction of the original ethereal solution with sodium hydroxide yielded only a trace of an amorphous, yellow solid, and on finally removing the ether only a small quantity of a light green, gelatinous mass was obtained.

---

[1] *Ann. chim. phys.* [7], 7, 227.
[2] *Ann.*, 271, 222 (1892).

Chloroform, Ethyl Acetate and Alcohol Extracts of the Resin.

These were all black, brittle solids, and nothing crystalline could be obtained from them.

III. Examination of the Shells.

The shells or husks from 22.5 kilograms of pumpkin seed amounted to 4680 grams, thus corresponding to 20.8 per cent. of the weight of the latter.

The material was ground and extracted by continuous percolation with hot alcohol. After the removal of the greater portion of the alcohol there remained a dark-colored oil. This was mixed with water and distilled with steam, but no volatile product was obtained. The contents of the distillation flask separated, on cooling, into an upper layer of fatty oil (*A*) and a lower aqueous liquid (*B*), the latter containing some resin (*C*).

The Fatty Oil (A).

The entire liquid contained in the distillation flask, consisting, as above described, of fatty oil and a lower aqueous portion, was shaken with light petroleum. The petroleum liquid was filtered to remove a small amount of resin, washed with water, dried with anhydrous sodium sulphate, and the solvent removed. A quantity (595 grams) of a dark green, fatty oil was thus obtained, which possessed the following constants: $d\ 20°/20° = 0.9236$; saponification value, 190.3; iodine value, 118.5. These figures are in close agreement with those afforded by both the expressed oil and that obtained from the "press-cake," and the constituents of the three oils were practically the same.

The Aqueous Liquid (B).

This liquid, which had a dark brown color, was filtered to remove a small amount of resin. It was then repeatedly extracted with ether, the combined ethereal liquids being washed, dried, and the solvent removed, when about 2 grams of a dark brown, resinous substance were obtained. The latter was redissolved in ether, and the ethereal solution extracted with alkalies, which removed the greater portion of the substance. It gave a violet coloration with ferric chloride and appeared to contain traces of salicylic acid, which had been definitely identified in a corresponding product from the "press-cake," but the amount in the present instance was too small to permit of its isolation.

The aqueous liquid was subsequently treated with a slight excess of basic lead acetate, which produced a voluminous, light brown precipitate. The latter was collected on a filter, well washed, and then suspended in water and decomposed by hydrogen sulphide. After removing the lead sulphide by filtration, a reddish brown liquid was obtained, which gave a dark brown coloration with ferric chloride, indicating the presence of some tannic matter. This liquid was concentrated under diminished pressure, but nothing separated on standing, and, when mixed with purified sawdust, and the dried mixture extracted with various solvents, it yielded nothing crystalline.

The filtrate and washings from the basic lead acetate precipitate possessed a light green color. This was due to the presence of a very small amount of copper, which, by a special test, was found to be contained in the original pumpkin seed.[1] After treatment with hydrogen sulphide for the removal of the excess of lead, and filtering, the liquid was concentrated under diminished pressure to a small bulk. It then had a reddish brown color and contained a quantity of sugar, since it readily yielded *d*-phenylglucosazone, melting at 208°. A portion of the liquid was mixed with purified sawdust and the dried mixture extracted successively with ether, ethyl acetate, and alcohol, but no crystalline substance was removed by these solvents. Another portion of the liquid was treated with dilute sulphuric acid in the manner described in connection with the corresponding liquid from the "press-cake." The products were the same as those yielded by the last-mentioned liquid.

The Resin (C).

The total amount of resinous material obtained from the shells of the pumpkin seed was about 10 grams. It formed a black, brittle mass, and, as already noted, was examined in connection with the larger amount of resin obtained from the "press-cake."

Summary and Conclusions.

In view of the somewhat extended details of the present investigation, a summary of the more important results may here be appended, together with a record of some physiological tests and the deductions therefrom.

---

[1] An account of the wide distribution of copper, in both the vegetable and animal kingdoms, is recorded in the *Am. J. Pharm.*, 77, 274 (1905).

The kernels of the pumpkin seed, separated as completely as possible from the shells, were subjected to strong hydraulic pressure, when they yielded a quantity of fatty oil, together with the so-called "press-cake." These products were then separately examined.

I. *The Fatty Oil.*—The amount of oil obtained from the kernels by expression corresponded to 19.3 per cent. of the weight of the entire seed. The entire seed, when ground and extracted with light petroleum, yielded 34.3 per cent. of fatty oil. The expressed oil, which was optically inactive, possessed the following constants: Specific gravity, 20°/20° = 0.9220; acid value, 3.4; saponification value, 189.4; iodine value, 119.7. The composition of the oil was approximately as follows:

Linoleic acid, as glyceride,	45 per cent.
Oleic acid, as glyceride,	25 "
Palmitic acid Stearic acid } as glycerides,	30 "
	100 "

The oil contains no myristic acid, as has previously been asserted, and of the two solid acids the palmitic acid is in somewhat the larger amount. It contains a very small amount of a phytosterol, $C_{27}H_{46}O$ (m. p. 162–163°), and apparently another substance of this class, having a lower melting point.

II. *The "Press-cake."*—This material was extracted with hot alcohol, and in the resulting product the presence of the following constituents was determined: (1) A quantity of fatty oil, corresponding to 8.7 per cent. of the weight of the entire seed, and agreeing closely in character with that obtained by expression; (2) soluble protein products; (3) a quantity of sugar; (4) a very small amount of salicylic acid; (5) resinous material, amounting to about 0.5 per cent. of the weight of the entire seed. From the resin there were isolated a very small amount of a phytosterol (m. p. 157–159°), apparently identical with that obtained from the expressed oil, and a new *monocarboxylic acid* (m. p. 99°), agreeing in composition with a hydroxycerotic acid, $C_{25}H_{51}O.CO_2H$, which yielded an *ethyl ester* melting at 61°.

III. *The Shells.*—These amounted to 20.8 per cent. of the weight of the entire seed. When extracted with hot alcohol they yielded a fatty oil (amounting to 2.6 per cent. of the weight of the entire seed), which agreed closely in character with that obtained from the kernels by expression. They also contained sugar and a very small amount of resinous material. With the exception of traces of copper, a complete examination of the shells disclosed the presence of no substance which is not contained in the kernel of the seed.

Physiological Tests.

It was finally deemed of interest to ascertain, if possible, whether either the fatty oil or the resin possesses the taenifuge properties which are ascribed to pumpkin seed. For this purpose some preliminary experiments were kindly conducted for us by Dr. H. H. Dale, Director of the Wellcome Physiological Research Laboratories, to whom our thanks are due.

The pure expressed oil of pumpkin seed, such as was used for our chemical investigation, was administered in doses of 30 cc., and under the usual conditions of a restricted diet, to two dogs that were known to be afflicted with tapeworm. After an interval of several hours, castor oil was given, but in neither of these cases could any tapeworm be found in the excreta.

One gram of the resin, obtained from the kernel of the seed as above described, was administered to a small dog which had been given no food for 20 hours. Nothing happened during the 6 hours following its administration, and the dog was then given 20 cc. of castor oil. This produced fairly copious, loose evacuations, in which isolated, macerated proglottides were detected, but no considerable length of tapeworm. The resin obtained from the shells or husks of the seed was given to another dog in about the same amount (0 9 gram) as in the preceding experiment, and under similar conditions, but with an equally negative result. While these experiments have thus shown the resin of pumpkin seed to be perfectly innocuous, they have, on the other hand, afforded no indication that it possesses anthelmintic properties.

Through the kindness of several medical practitioners in different parts of the country an opportunity was afforded us of testing the pumpkin seed oil in five cases of tapeworm, four of which occurred in children. The amount of oil administered varied from half a fluidounce to two ounces (15 to 60 cc.), and, although the dose was in some cases repeated, in no instance did it effect the complete removal of the worm. In one of these cases, that of a child of seven years, in which 2 ounces (60 cc.) of the oil had removed a portion of the worm, a trial was subsequently made of the resin from the seed. One gram of this material (representing approximately 200 grams of pumpkin seed) was administered in the early morning, while fasting, and was followed in two hours by a dose of castor oil. No ill effects were observed, and, although the child was purged several times, neither the worm nor any fragment of it appeared.

In conclusion it may be said that the results of the above-described experiments do not enable us to confirm the recorded statements respecting the efficacy of either the fatty oil or the resin of pumpkin seed as a taenifuge. As it is evident that these seeds contain no principle exhibiting marked physiological activity, any value which they may actually possess, when administered in substance for the purpose indicated, would therefore appear to be attributable to a mechanical action. In any case, the remedial value of pumpkin seeds cannot be considered such as to justify their recognition by a national pharmacopoeia.

CHEMICAL EXAMINATION OF WATERMELON SEED.

BY FREDERICK B. POWER AND ARTHUR H. SALWAY.

Received January 13, 1910

The seeds of the watermelon (*Cucurbita citrullus*, Linné) have been employed to some extent medicinally on account of their diuretic properties, but chiefly as a domestic remedy. So far as known to us, they have never been examined chemically. Lewkowitsch[1] has briefly noted the physical and chemical constants of the fatty oil, and of the mixed fatty acids obtained therefrom, but makes no statement regarding the composition of the oil, and no further information concerning this product appears to be available.

As many of the plants belonging to the family of *Cucurbitaceae* contain in some of their parts substances which possess a considerable degree of physiological activity, it was deemed desirable to submit the seeds of the watermelon to a complete chemical examination. Such an investigation appeared, furthermore, of interest from the point of view of comparing the constituents of these seeds with those of the common pumpkin (*Cucurbita pepo*, Linné), which have recently been completely examined by us.[2]

EXPERIMENTAL.

The material employed was obtained from the United States and consisted of fresh watermelon seeds of good quality.

A portion of the crushed seed was first tested for the presence of an alkaloid by means of Prollius' fluid, but with a negative result.

For the purpose of a complete investigation, 22.5 kilograms of the seed were crushed and the shells separated as completely as possible from the kernels. The shells amounted to 10.95 kilograms, thus corresponding to 48.7 per cent. of the weight of the seed. The ground kernels were then subjected to strong hydraulic pressure, when 1665 grams of fatty oil were obtained, corresponding to 7.4 per cent. of the weight of the entire seed. The so-called "press-cake" remaining after the removal of the oil amounted to 8.88 kilograms. These operations, connected with the expression of the oil, were carefully conducted for us by Messrs. Stafford, Allen & Sons, of London, to whom our thanks are due.

---

[1] "Chemical Technology and Analysis of Oils, Fats and Waxes," 3rd Edit., Vol II, p. 511.

[2] THIS JOURNAL, 32, 346.

A portion of the entire seed, when ground and extracted in a Soxhlet apparatus with light petroleum (b. p. 30–45°), yielded 19.0 per cent. of fatty oil.

I. Examination of the Expressed Oil.

The expressed oil of watermelon seed has a light yellow color and, unlike that from pumpkin seed, is completely devoid of fluorescence. The constants of the oil were determined with the following results:

	Expressed oil.	Oil extracted by petroleum.
Specific gravity 20°/20°	0.9233	0.9219
Acid value	3.9	3.6
Saponification value	191.8	189.9
Iodine value	121.1	121.8

For a complete chemical examination of the oil, 250 grams of it were employed. It was first subjected to distillation with steam, but the distillate contained no volatile oil nor any acid.

Hydrolysis of the Oil.

The oil which had been subjected to distillation with steam, as above described, was separated from the water, the latter then extracted with ether to recover a small amount of suspended oil, and, after adding this to the main portion, the whole was hydrolyzed by heating with an alcoholic solution of 70 grams of potassium hydroxide. The greater portion of the alcohol was then removed, water added, and the alkaline liquid repeatedly extracted with ether. The ethereal liquids were united, washed with a little water, dried with anhydrous sodium sulphate, and the ether removed, when about 0.5 gram of a light yellow oil was obtained, which soon solidified. The solid product, after three crystallizations from a mixture of ethyl acetate and alcohol, separated in pearly leaflets, melting at 163–164°. After drying at 105° it was analyzed:

0.0881 gave 0.2667 CO_2 and 0.0905 H_2O. C = 82.6; H = 11.4.

$C_{20}H_{34}O$ requires C = 82.8; H = 11.7 per cent.

This substance, when dissolved in chloroform with a little acetic anhydride, and a drop of sulphuric acid subsequently added, gave a blue coloration, rapidly changing to green, and finally to brown. It is evidently a phytosterol.

The Fatty Acids.

The alkaline, aqueous solution of potassium salts, which had been extracted with ether as above described, was acidified with sulphuric acid and the mixture distilled with steam. The distillate, however, contained no volatile acid. The fatty acids remaining in the distillation flask were taken up with ether, the ethereal solution being washed, dried, and the solvent removed. For the purpose of determining the constants of the mixed fatty acids, a portion was heated for some time at 100° under diminished pressure, in order to remove the last traces of ether, after which the following results were obtained: M. p. (complete fusion), 35°; d 50°/50° = 0 8894; neutralization value, 198.2; iodine value, 118.2. Optically inactive. A determination of the acetyl value indicated the absence of hydroxy acids.

The mixed fatty acids, which consisted of a liquid and a solid portion, were first partially separated by filtration with the aid of a pump. The solid acids were then fractionally crystallized from alcohol until no further separation could be effected by this means. The least soluble fraction melted at 66–68°, and was considerable in amount. In order to ascertain whether this fraction was homogeneous, it was dissolved in hot alcohol and a measured portion of concentrated, aqueous barium acetate added, drop by drop, with constant stirring. The mixture was then filtered, while still hot, with the aid of a pump, and the precipitate washed with a little hot alcohol. The whole operation was then repeated, and in this manner four successive fractions of barium salt were obtained. The acids liberated from each of these fractions were crystallized once from alcohol, when they had the following melting points: 69–70°, 69–70°, 67–69°, 65–67°. The acid melting at 69–70° separated in glistening, pearly leaflets and was analyzed:

0.1267 gave 0.3522 CO_2 and 0 1448 H_2O. C = 75 8; H = 12.7.

0.5155 neutralized 18.1 cc. 0.1 *N* KOH. Neutralization value = 197.0°.

$C_{18}H_{36}O_2$ requires C = 76.1; H = 12.7 per cent. Neutralization value = 197.5.

It is thus evident that the substance melting at 69–70° was stearic acid, and that no acid of higher carbon content was present.

All the portions of acid obtained in the course of the original fractionation which melted below 66–68° were united and fractionally precipitated with barium acetate in the manner previously described. Six fractions of barium salt were thus obtained, from which the acids were subsequently liberated. The last of these fractions of acid was oily, and to a large extent unsaturated, while the remaining five fractions, after being once crystallized from alcohol, melted at 66–68°, 65–67°, 65–67°, 64–66°, and 57–58°, respectively. Each of these fractions was titrated, with the following results:

Fraction 1 (m. p. 66–68°), 0.2661 neutralized 9.5 cc. 0.1 *N* KOH. N. V. = 200.3.

Fraction 2 (m. p. 65–67°), 0.1356 neutralized 4.8 cc. 0.1 *N* KOH. N. V. = 198.6.

Fraction 3 (m. p. 65–67°), 0.1828 neutralized 6.5 cc. 0.1 *N* KOH. N. V. = 199.5.

Fraction 4 (m. p. 64–66°), 0.0876 neutralized 3.15 cc. 0.1 *N* KOH. N. V. = 201.8.

Fraction 5 (m. p. 57–58°), 0.1707 neutralized 6.35 cc. 0.1 *N* KOH. N. V. = 208.7.

$C_{18}H_{36}O_2$ requires a neutralization value of 197.5.
$C_{16}H_{32}O_2$ requires a neutralization value of 219.1.

From the above results it was evident that fractions 1–4, inclusive, consisted, to a large extent, of stearic acid, while fraction 5 would appear to have contained about equal parts of stearic and palmitic acids.

It may therefore be concluded that the solid fatty acids of watermelon seed oil consist only of palmitic and stearic acids, the latter being present in the larger proportion.

The liquid acids, which had been separated from the solid portion as previously described, constituted the larger proportion of the total fatty acids. In order to separate the small amount of saturated acids still contained in the liquid portion, the whole was converted into a lead salt and this extracted with ether. The portion of lead salt soluble in ether yielded 145 grams of liquid acid, which possessed the following constants: *d* 20°/20° = 0.9027; b. p. 233–240°/20 mm.; neutralization value, 200.1; iodine value, 142.1.

0.1230 gave 0.3433 CO_2 and 0.1293 H_2O. C = 76.1; H = 11.7.
$C_{18}H_{34}O_2$ requires C = 76.6; H = 12.1 per cent.
$C_{18}H_{32}O_2$ requires C = 77.1; H = 11.4 per cent.

The above results indicated that the liquid acid consisted of a mixture of unsaturated acids, and with the endeavor to effect their separation a method was employed which depended on the fractional precipitation of their barium salts. Five fractions of barium salt were thus obtained, each of which was shaken with hydrochloric acid in the presence of ether, the ethereal solution being subsequently washed, dried, and the solvent removed. After heating for a time at 100° under diminished pressure, in order to remove the last traces of ether, the iodine value of the several fractions of acid was determined:

Fraction I 0.1035 of acid absorbed 0.1455 I. Iodine value = 140.6.
Fraction II. 0.1573 of acid absorbed 0.2249 I. Iodine value = 143.0.
Fraction III. 0.1436 of acid absorbed 0.2073 I. Iodine value = 144.4
Fraction IV. 0.0983 of acid absorbed 0.1417 I. Iodine value = 144.2.
Fraction V. 0.0987 of acid absorbed 0.1417 I. Iodine value = 143.6.
$C_{18}H_{34}O_2$ requires an iodine value of 90.1.
$C_{18}H_{32}O_2$ requires an iodine value of 181.4.

The first fraction still contained a small amount of saturated acid, while the iodine values of the remaining four fractions indicated that the latter were practically identical in composition. It was, however, also apparent that a separation of the acids had not been effected by the above-described method.

From the iodine values above noted it could be concluded that the mixture of unsaturated acids consisted of oleic and linoleic acids in approximately equal proportions. In order to confirm this assumption, 30 grams of the mixture were oxidized in alkaline solution with an equal weight of potassium permanganate. The product of oxidation was digested with large quantities of ether, which extracted a substance melting at 126–128° and which, after crystallization from alcohol, separated in small, glistening leaflets melting at 128°.

0.1039 gave 0.2594 CO_2 and 0.1075 H_2O. C = 68.1; H = 11.5.

$C_{18}H_{36}O_4$ requires C = 68.4; H = 11.4 per cent.

This substance was evidently dihydroxystearic acid, and its formation established the presence of oleic acid in the mixture of liquid acids.

The oxidation product, after extraction with ether, was heated with large quantities of water, and the liquid filtered while hot. These deposited a pure white, crystalline substance, melting at 154–155°, which, after crystallization from alcohol, separated in small, thin needles, melting at the same temperature.

0.1138 gave 0.2574 CO_2 and 0.1068 H_2O. C = 61.7; H = 10.4.

$C_{18}H_{36}O_6$ requires C = 62.1; H = 10.3 per cent.

This substance was thus identified as tetrahydroxystearic acid (sativic acid), and its formation established the presence of linoleic acid in the mixture of liquid acids. As no hexahydroxystearic acid could be isolated from the product of oxidation, it may be concluded that linolenic acid is not a constituent of the oil.

II. Examination of the Press-cake.

The so-called "press-cake" resulting from the expression of 22.5 kilograms of watermelon seeds, deprived as completely as possible of the shells, amounted, as previously noted, to 8.88 kilograms. This was completely extracted with hot alcohol, when, after the removal of the greater portion of the alcohol, a thin, dark brown, oily extract was obtained, amounting to 1644 grams. It evidently contained a considerable quantity of fatty oil which had escaped expression from the seed, and which was removed by treating the extract with light petroleum (b. p. 30–45°). The amount of fatty oil obtained in this way was 1340 grams, thus corresponding to 81.5 per cent. of the total alcoholic extract. Its constants were as follows: *d* 20°/20° = 0.9328; saponification value, 191.4; iodine value, 112.7.

The fatty oil obtained from the press-cake, as above described, would naturally be expected to be similar in composition to that obtained from the seed by expression, and its examination proved this to be the case. It was found to contain a very small amount of a phytosterol, melting at 160°, and the mixed fatty acids obtained on hydrolysis possessed the following constants: m. p., 34°; *d* 50°/50° = 0.8916; neutralization value, 197.6; iodine value, 129.5. These acids, like those obtained from the expressed oil, consisted of a mixture of palmitic, stearic, oleic and linolic acids.

The portion of the alcoholic extract which remained undissolved by treatment with light petroleum was subjected to distillation with steam, but no volatile product was obtained. The contents of the distillation flask then consisted of a dark colored aqueous liquid (*A*) and a quantity of a black resin (*B*), which were separated by filtration and the resin well washed with water.

The Aqueous Liquid (A).

The aqueous liquid was repeatedly extracted with ether, the ethereal liquids being washed, dried, and the solvent removed. About 0 5 gram of a viscid, brown oil was thus obtained, which deposited nothing in the cold, and which, in alcoholic solution, gave with ferric chloride a green coloration. The oily product was digested with a large volume of light petroleum, but no crystalline substance could be isolated from it. It was thus ascertained that the seed of the watermelon, unlike those of the pumpkin, do not contain salicylic acid.

Treatment with Basic Lead Acetate.

The aqueous liquid, which had been extracted with ether as above described, was subsequently treated with basic lead acetate, which yielded a yellowish brown precipitate. The latter was collected on a filter, thoroughly washed, and then suspended in water and decomposed by hydrogen sulphide. On filtering the mixture and concentrating the filtrate under diminished pressure, a reddish brown liquid was obtained, which gave a bluish black coloration with ferric chloride, thus indicating the presence of tannin. As the liquid deposited only a little amorphous material on standing, it was finally mixed with purified sawdust and the dried mixture extracted successively in a Soxhlet apparatus with ether, ethyl acetate and alcohol. These solvents, however, did not effect the separation of any crystalline substance.

The filtrate from the basic lead acetate precipitate was treated with hydrogen sulphide for the removal of the excess of lead, filtered, and this filtrate concentrated under diminished pressure. A reddish brown, sirupy liquid was thus obtained, which contained a large amount of sugar, since it readily yielded *d*-phenylglucosazone, melting at 210°. The liquid gave a precipitate with potassium-mercuric iodide, and on heating with alkalies evolved ammonia, but these reactions were evidently due to protein products and not to the presence of an alkaloid, since the entire seed, when tested for substances of this class by means of Prollius' fluid, gave a perfectly negative result.

A portion of the aqueous liquid which had been purified by treatment with basic lead acetate, as above described, was heated for some time in a reflux apparatus with such an amount of sulphuric acid that the latter represented 5 per cent. by weight of the mixture. During the operation a quantity of resinous material separated, which was quite insoluble in the usual organic solvents. On subsequently passing steam through the liquid a slightly acid distillate was obtained, in which the presence of formic and acetic acids was determined. The acid, aqueous liquid which remained in the distillation flask was repeatedly extracted with ether, which, however, removed only traces of brown, amorphous material. No evidence was thus obtained of the presence in the aqueous liquid of any definite substance of a glucosidic nature.

The Resin (B).

The resin from the "press-cake" amounted to 70 grams. The greater portion of this material (68 grams) was digested with hot alcohol, then mixed with purified sawdust, and the thoroughly dried mixture extracted successively in a Soxhlet apparatus with various solvents, when the following amounts of extract, dried at 100°, were obtained:

Petroleum (b. p. 30–45°) extracted	27.0 grams	=	39.7 per cent.
Ether	"	3.8 "	=	5.6 "
Chloroform	"	3.0 "	=	4.4 "
Ethyl acetate	"	2.2 "	=	3.2 "
Alcohol	"	15.5 "	=	22.8 "
Total,		51.5 "	=	75.7 "

By this process of extraction a considerable portion of the resin had evidently been rendered insoluble.

Petroleum Extract of the Resin.

This was a dark-colored, viscid product. It was heated in a reflux apparatus with an excess of an alcoholic solution of potassium hydroxide, the greater portion of the alcohol then removed, water added, and the alkaline mixture extracted with ether. The ethereal liquid was washed, dried, and the solvent removed, when a very small quantity (0.2 gram) of a light yellow solid was obtained. This was crystallized from a mixture of ethyl acetate and alcohol, when it melted at 158–159°. It was a phytosterol and apparently identical with that previously isolated from the expressed oil of the seed.

The alkaline, aqueous liquid, from which the above-mentioned phytosterol had been separated, was acidified with sulphuric acid and extracted with ether. During the extraction a small quantity of resinous matter separated, which was removed by filtration. This was dried on a porous tile, and then dissolved in pyridine, when it yielded a crystalline substance which, after a few crystallizations from the same solvent, separated in colorless, prismatic needles, melting and decomposing at about 260°. It was found to be identical with a new substance, $C_{24}H_{40}O_4$, which was subsequently isolated from the ether extract of the resin, as described below.

The ethereal liquid, as above obtained, was washed, dried, and the solvent removed, when it yielded a mixture of fatty acids. This was distilled under diminished pressure, when it passed over between 230 and 245°/25 mm., leaving only a small amount of resin. The distilled product, on cooling, became partially solid. The solid portion was therefore separated by filtration, with the aid of the pump, and crystallized from alcohol, when it was obtained in glistening plates, melting at 60–62°.

0.3561 neutralized 32.2 cc. 0.1 *N* KOH. Neutralization value = 208.0.
$C_{18}H_{36}O_2$ requires a neutralization value of 197.5.
$C_{16}H_{32}O_2$ requires a neutralization value of 219.1.

The product evidently consisted of a mixture of palmitic and stearic acids in about equal proportions.

The liquid acids which had been separated from the solid portion by filtration were for the most part unsaturated, since they readily absorbed bromine, and the presence of oleic acid was also indicated by the behavior towards nitric acid.

The fatty acids contained in the petroleum extract of the resin were therefore the same as those obtained from the expressed oil of watermelon seeds.

Ether Extract of the Resin.

Isolation of a New Alcohol, Cucurbitol, $C_{24}H_{40}O_4$.—The ether extract of the resin was a dark brown, soft mass, and amounted to only 3.8 grams. It was digested with cold alcohol, which removed the coloring matter, while the greater portion of the material remained as a yellowish brown powder. This was collected on a filter and washed with a little cold alcohol, after which it was dissolved in warm pyridine. From this solution a substance separated in the form of radiating clusters of colorless needles, which, when slowly heated, melted and decomposed at 260°. The substance, after drying at 110°, was analyzed:

0.0626 gave 0.1680 CO_2 and 0.0587 H_2O. C = 73.2; H = 10.4
$C_{24}H_{40}O_4$ requires C = 73.5; H = 10.2 per cent.

The substance is thus seen to agree in composition with the formula $C_{24}H_{40}O_4$. When dissolved in chloroform with a little acetic anhydride, and a drop of concentrated sulphuric acid subsequently added, a blue coloration is produced, which slowly becomes greenish, and finally dull brown. When heated with acetic anhydride it yielded an acetyl derivative which crystallized in radiating clusters of fine needles, melting at 150°. The acetyl derivative is very soluble in ethyl acetate and moderately so in alcohol, but the amount available was not sufficient for analysis.

No substance of the formula $C_{24}H_{40}O_4$, possessing properties similar to those above described, has hitherto been recorded. With consideration, therefore, of the source and alcoholic nature of the new compound, it is proposed to designate it *cucurbitol.*

It is of interest to note, in this connection, that two substances of alcoholic nature, which appear to be closely related to cucurbitol, have recently been isolated in these laboratories. One of these was obtained from the resin of *Grindelia camporum*, Greene, and agrees in composition with the formula $C_{23}H_{38}O_4$. It melts at 256–257°, and yields an acetyl derivative melting at 161°.[1] This compound, which was not previously named, may now be conveniently designated *grindelol.* The other substance was obtained from jalap resin and possesses the formula $C_{21}H_{34}O_4$.[2] The latter compound, designated *ipurganol,* melts at 222–225° and yields an acetyl derivative melting at 166–167°. The three substances, cucurbitol, grindelol, and ipurganol, show slight differences in their color reactions when subjected to the above-mentioned test in chloroform solution with acetic anhydride and concentrated sulphuric acid. Thus ipurganol gives at first a purplish pink coloration, changing to blue, then becoming bright green, and finally brown, while grindelol gives at first a blue color, which changes to a duller green than the preceding, and finally becomes brown, and in the case of cucurbitol the intermediate greenish tint is still less pronounced. In view of the composition and character of these three new compounds, it is evident that they are members of a homologous series, which is represented by the general formula $C_nH_{2n-8}O_4$.

Chloroform, Ethyl Acetate and Alcohol Extracts of the Resin.

The chloroform and ethyl acetate extracts were both very small in amount (3.0 and 2.2 grams respectively), and, like the alcohol extract of the resin, formed brittle, black solids. They were all carefully examined, but nothing definite could be isolated from them.

III. Examination of the Shells.

The shells from 22.5 kilograms of watermelon seeds amounted to 10.95 kilograms, thus corresponding to 48.7 per cent. of the weight of the seed. This material was ground and extracted by continuous percolation with hot alcohol. After the removal of the greater portion of the alcohol, a dark-colored, oily product was obtained, which contained some resin in suspension. The entire amount of extract (907 grams) was first mixed with a large volume of light petroleum, in order to effect the separation of the fatty oil (*A*). The portion of extract remaining undissolved by the petroleum may be designated as (*B*).

The Fatty Oil (A).

The petroleum solution of the fatty oil was filtered, dried with anhydrous sodium sulphate, and the solvent removed. A dark green, opaque oil was thus obtained, which amounted to 750 grams, or 82.7 per cent. of the total alcoholic extract. It possessed the following constants: d 20°/20° = 0.9351; saponification value, 191.3; iodine value, 114.6.

---

[1] Compare *Proc. Am. Pharm. Assoc.*, 55, 342 (1907).

[2] THIS JOURNAL, 32, 89.

For the examination of the fatty oil 150 grams of it were employed. This was brought into a flask with a little water and steam passed through the mixture, but the distillate contained only traces of volatile acid.

Hydrolysis of the Oil.

The fatty oil remaining in the distillation flask after the above-mentioned treatment with steam was separated from the water and hydrolyzed by heating with an alcoholic solution of 40 grams of potassium hydroxide. The greater portion of the alcohol was then removed, water added, and the alkaline solution extracted repeatedly with ether. The ethereal liquids were united, washed with water, dried with anhydrous sodium sulphate, and the solvent removed. About 0.5 gram of a solid substance was thus obtained, which crystallized readily from a mixture of ethyl acetate and alcohol. It first melted at 140°, and after a second crystallization separated in pearly leaflets, melting at 141–142°. After drying at 105° it was analyzed:

0.0970 gave 0.2930 CO_2 and 0.1012 H_2O. C = 82.4; H = 11 6.
$C_{20}H_{34}O$ requires C = 82 8; H = 11.7 per cent.

This substance is thus seen to be a phytosterol, and its identity was further confirmed by the characteristic color reactions.

The Fatty Acids.

The alkaline, aqueous solution of potassium salts, which had been extracted with ether as above described, was acidified with sulphuric acid and again extracted with ether, the ethereal solution being washed, dried, and the solvent removed. A dark brown, semi-solid mass of fatty acids was thus obtained, which possessed the following constants: M. p., 32°; d 50°/50° = 0.8968; neutralization value, 200 2; iodine value, 115.8.

The acid, aqueous liquid which had been extracted with ether was distilled with steam, but the distillate contained only traces of volatile acid.

The mixed fatty acids were first separated into a solid and a liquid portion by filtration with the aid of a pump. The solid portion was then fractionally crystallized from alcohol, when the least soluble fraction, on further crystallization, melted successively at 63–66°, 66–68°, 68–69°, and finally at 71°. It was thus evident that some acid of higher carbon content than stearic acid was present, and the substance melting at 71° was analyzed:

0.1060 gave 0.2968 CO_2 and 0.1201 H_2O. C = 76.4; H = 12.6.
$C_{18}H_{36}O_2$ requires C = 76.1; H = 12.7 per cent.
$C_{20}H_{40}O_2$ requires C = 76.9; H = 12.8 per cent.

This substance thus appeared to consist of a mixture of stearic and arachidic acids, and the separation of the latter in a pure state was subsequently accomplished by the fractional distillation of the solid portion of mixed fatty acids. On distilling the solid acids under diminished pressure, they began to boil at 230°/18 mm., but nearly the entire amount passed over between 233 and 240°/18 mm., while a small final fraction was collected at 240–250°/18 mm. The last-mentioned fraction readily solidified on cooling, and was then crystallized twice from ethyl acetate, from which it separated in rosettes of glistening leaflets, melting at 76–78°.

0.0935 gave 0.2633 CO_2 and 0.1077 H_2O. C = 76.8; H = 12 8.
$C_{20}H_{40}O_2$ requires C = 76 9; H = 12.8 per cent

The identity of this substance as arachidic acid was thus established.

The fraction of acid distilling at 230–233°/18 mm. melted at 59–60°, while that collected between 233 and 240°/18 mm. melted at 62–64°. Both of these fractions consisted of mixtures of palmitic and stearic acids.

The liquid portion of the mixed fatty acids was highly unsaturated, and, like the corresponding product from the expressed oil of the seed, evidently consisted of a mixture of oleic and linoleic acids.

Portion of Alcoholic Extract Insoluble in Petroleum (B).

This portion of the original extract of the shells formed a black, resinous mass, amounting to 150 grams. It was mixed with water and distilled with steam, but the distillate contained only traces of volatile acid. The contents of the distillation flask then consisted of a light yellow, aqueous liquid and a quantity of a black resin. These were separated by filtration and the resin well washed with water.

The Aqueous Liquids.

The above-mentioned, yellow, aqueous liquid was repeatedly extracted with ether, which removed about 1 gram of a brownish yellow oil. On digesting this product with water, the resulting liquid gave a greenish coloration with ferric chloride. The oily product was practically insoluble in water and only partially soluble in sodium carbonate, but dissolved completely in a solution of sodium hydroxide, and was therefore phenolic in character. It was distilled under diminished pressure, whereby some resinous material was removed, and then benzoylated. A crystalline solid melting at 205–210° was thus obtained, but the amount was much too small for further examination.

The aqueous liquid was subsequently treated with a slight excess of basic lead acetate, which yielded a relatively small amount of a yellowish precipitate. This was collected, washed, suspended in water, and decomposed by hydrogen sulphide. On filtering the mixture a liquid was obtained which gave a bluish black coloration with ferric chloride, indicating the presence of tannin, but no definite compound could be isolated from it.

The filtrate from the basic lead acetate precipitate possessed a light green color. This was due to the presence of a very small amount of copper, which, by a special test, was subsequently found to be contained in the original watermelon seed.[1] After treatment with hydrogen sulphide for the removal of the excess of lead, and filtering, the liquid was concentrated under diminished pressure. A light yellow sirup was thus obtained, which deposited nothing crystalline on standing. It contained a quantity of sugar, since it readily reduced Fehling's solution, and yielded *d*-phenylglucosazone, melting at 212–213°.

The aqueous liquid, when heated with alkalies, developed ammonia, which was evidently due to the presence of soluble protein compounds, but it was observed that a peculiar basic odor was also produced. In order to ascertain whether by this treatment any volatile base other than ammonia was formed, a portion of the liquid was heated with baryta in a current of steam, the volatile product being collected in hydrochloric acid. The salt thus obtained, which was small in amount, was converted into the platinum compound, and the latter, after drying in a vacuum over sulphuric acid, was analyzed:

0.0785 of the salt gave, on ignition, 0.0340 Pt. Pt = 43 3.
$(NH_4)_2PtCl_6$ requires Pt = 43.9 per cent.

This salt, therefore, was practically pure ammonium chloroplatinate.

Another portion of the aqueous liquid was heated in a reflux apparatus with such an amount of sulphuric acid that the latter represented 5 per cent. of the weight of the mixture. On distilling the product with steam, only small quantities of formic and acetic acid were obtained, and the contents of the distillation flask, when subsequently extracted with ether, likewise yielded nothing which would indicate the presence of a glucoside in the original aqueous liquid.

A portion of the aqueous liquid was finally mixed with purified sawdust and the thoroughly dried mixture extracted successively in a Soxhlet apparatus with ether, ethyl acetate and alcohol, but no definite substance could be isolated by means of these solvents.

The Resin.

The black, resinous material contained in the portion of alcoholic extract which was insoluble in petroleum, and which had been separated from the aqueous liquid, as above described, amounted to 68 grams. The greater part (66 grams) of this material was digested with alcohol, then mixed with purified sawdust, and the thoroughly dried mixture extracted successively in a Soxhlet apparatus with various solvents. The results were as follows:

---

[1] An account of the wide distribution of copper, in both the vegetable and animal kingdoms, is recorded in the *Am. J. Pharm.*, 77, 274 (1905).

Petroleum (b. p. 30–45°)	extracted	25.6 grams	= 38.8 per cent.
Ether	"	3.2 "	= 4.8 "
Chloroform	"	9.2 "	= 13.9 "
Ethyl acetate	"	3.4 "	= 5.2 "
Alcohol	"	7.4 "	= 11.2 "
Total,		48.8 "	= 73.9 "

Petroleum Extract of the Resin.

This extract was a dark, viscid liquid. On the addition of ether a small quantity of a gelatinous substance separated, which was removed by filtration. This substance was very sparingly soluble in alcohol, but readily soluble in hot acetic acid, and also in pyridine, from both of which solvents it was again deposited in a gelatinous form.

The portion of the extract which was soluble in ether was heated with an alcoholic solution of potassium hydroxide. After removing the alcohol, water was added and the alkaline liquid extracted with ether. The ethereal liquid, after the removal of the solvent, yielded about 0.5 gram of a light yellow solid, which, when crystallized from a mixture of ethyl acetate and alcohol, separated in glistening leaflets, melting at 138–140°. The melting point and color reactions of this substance indicated that it was identical with the phytosterol, $C_{20}H_{34}O$ (m. p. 141–142°), obtained from the fatty oil of the shells of watermelon seeds.

The alkaline solution of potassium salts, after extraction with ether, was acidified with sulphuric acid and again treated with ether, the ethereal liquid being washed, dried and the solvent removed. The fatty acids thus obtained were distilled under diminished pressure, when the greater portion passed over between 235 and 240°/20 mm., a small fraction having also been collected at 240–260°/20 mm. The fraction 235–240°/20 mm. became partially solid on cooling. The solid portion was therefore removed and crystallized from alcohol, when, after the first crystallization, it melted at 55–58°.

0.3334 neutralized 12.05 cc. 0.1 *N* KOH. Neutralization value = 202.8.

$C_{18}H_{36}O_2$ requires a neutralization value of 197.5.

$C_{16}H_{32}O_2$ requires a neutralization value of 219.1.

It was thus evident that the above portion of solid acid consisted of a mixture of palmitic and stearic acids, the former predominating.

The liquid portion of fatty acids from the fraction 235–240°/20 mm., when tested with nitric acid, was found to contain some oleic acid.

0.2331 absorbed 0.3301 iodine. Iodine value = 141.6.

These liquid fatty acids, therefore, like those contained in the expressed oil of watermelon seeds, evidently consisted of a mixture of oleic and linoleic acids.

The small fraction of acid collected at 240–260°/20 mm. solidified in the receiver. After two crystallizations from alcohol it separated in glistening leaflets, melting at 76–77°. This substance was identified as arachidic acid.

Ether Extract of the Resin.

This extract was a dark brown solid and very small in amount (3.2 grams). It was digested with cold alcohol, which removed the coloring matter, leaving a light brown, amorphous powder. On treating the latter with pyridine a few needle-shaped crystals were deposited, together with some amorphous, brown material. The crystalline substance, which was mechanically separated, melted and decomposed at 260°, and yielded an acetyl derivative melting at 150°. It gave the characteristic color reaction of *cucurbitol*, $C_{24}H_{40}O_4$, and was identical in every respect with the latter compound, as isolated from the "presscake" of watermelon seeds.

Chloroform, Ethyl Acetate and Alcohol Extracts of the Resin.

These were all dark colored, brittle solids, from which no crystalline substance could be obtained.

Summary.

The results of the present investigation of watermelon seeds may be summarized as follows:

The seeds contain no alkaloid, and no evidence was obtained of the presence of a glucoside.

1. *The Fatty Oil.*—The amount of oil obtained from the kernels by expression corresponded to 7.4 per cent. of the weight of the entire seed. The entire seed, when ground and extracted with light petroleum, yielded 19.0 per cent. of fatty oil. The amount of the latter is, therefore, very much less than was obtained by us from pumpkin seed.[1] The expressed oil, which was optically inactive, possessed the following constants: Specific gravity, 20°/20° = 0.9233; acid value, 3.9; saponification value, 191.8; iodine value, 121.1. The composition of the oil was approximately as follows:

Linoleic acid, as glycerides,	45	per cent.
Oleic acid, as glyceride,	25	"
Palmitic acid Stearic acid } as glycerides,	30	"
	100	"

Of the two solid acids, the stearic acid is in predominating amount. The oil contains, furthermore, a very small amount of a phytosterol, $C_{20}H_{34}O$ (m. p. 163–164°). It is thus seen that this oil agrees very closely in composition with the expressed oil of pumpkin seed examined by us.[1]

---

[1] THIS JOURNAL, 32, 351.

II. *The "Press-cake."*—This material was extracted with hot alcohol, and in the resulting extract the presence of the following constituents was determined: (1) A quantity of fatty oil, corresponding to about 6 per cent. of the weight of the entire seed, and agreeing closely in character with that obtained by expression; (2) soluble protein products; (3) a quantity of sugar; (4) resinous material, amounting to about 0.3 per cent. of the weight of the entire seed. From the resin there were isolated a very small amount of a phytosterol (m. p. 158–159°), and a new alcohol, designated *cucurbitol*, $C_{24}H_{40}O_4$ (m. p. 260°), which yields an acetyl derivative melting at 150°. Cucurbitol appears to be closely related to two other crystalline alcohols recently isolated in these laboratories, namely, *grindelol*, $C_{23}H_{38}O_4$ (m. p. 256–257°), from *Grindelia camporum*, which yields an acetyl derivative melting at 161°, and *ipurganol*, $C_{21}H_{31}O_4$ (m. p. 222–225°), from jalap resin, which yields an acetyl derivative melting at 166–167°. These three alcohols are evidently members of a homologous series, which is represented by the general formula $C_nH_{2n-8}O_4$.

III. *The Shells.*—These amounted to 48.7 per cent. of the weight of the entire seed. They contained a quantity of fatty oil, which was similar in character to that obtained from the kernels by expression, but, in addition to the fatty acids obtained from the latter, a small amount of arachidic acid was isolated. The resinous material contained in the shells corresponded to about 0.3 per cent. of the weight of the entire seed, and from it, besides a mixture of fatty acids, very small quantities of a phytosterol (m. p. 138–140°) and *cucurbitol*, $C_{24}H_{40}O_4$, were separated. It was observed that these shells, like those of the pumpkin seed, contain traces of copper.

In order to ascertain whether the resin obtained from watermelon seed possesses any physiological activity, some tests were kindly conducted for us by Dr. H. H. Dale, Director of the Wellcome Physiological Research Laboratories. The resin, both from the kernels and the shells of the seed, was administered to a dog in amounts of one gram each, but no obvious effect was produced, and it may therefore be considered quite innocuous.

THE CONSTITUTION OF RETENE AND ITS DERIVATIVES.

By John E. Bucher.

Received January 13, 1910.

In the early part of the work in this laboratory on the condensation of aromatic propiolic acids to derivatives of 1-phenyl-2,3-naphthalenedicarboxylic acid,[1] much difficulty was experienced in determining the structure of the latter compounds. They could be transformed into carboxylic acids of diphenyl, diphenyleneketone and fluorene. A comparatively small number of such acids are described in the literature and in some cases the structure given is evidently uncertain or else incorrect. They did not aid materially in determining the structure of the naphthalene products. Later in the work, very efficient methods for determining the nature of the products under investigation were found. These methods were found equally applicable for determining the constitution of the derivatives of diphenyl, diphenyleneketone and fluorene, as well as the substances of which these are oxidation products.

---

[1] This Journal, 32, 358.

It was found, for instance, that the constitution of retene could be shown very easily by applying three of these methods.[2] The first method used was that of oxidizing substances in pyridine solution with potassium permanganate. The second depends on the fact that diphenyleneketone-carboxylic acids are very easily oxidized to benzene polycarboxylic acids by alkaline potassium permanganate, if the oxidation is finished by means of fuming nitric acid, aided by the catalytic action of manganese nitrate. The third depends on the fact that when diphenyleneketone-carboxylic acids are heated with potassium hydroxide, the ring breaks in such a way as to have the carboxyl groups as far apart as possible.

Retene, $C_{18}H_{18}$, was examined early in the work, hoping that it would be of service in connection with the above investigation. It is designated as 8-methyl 5-isopropylphenanthrene (I) in such standard works as those of Beilstein and V. von Richter. The numerous derivatives are also assigned corresponding structural formulas, in nearly all cases, without even a question mark, as is shown in the example of reteneketone in Richter's "Lexikon der Kohlenstoffverbindungen."

On looking up the original work of Bamberger and Hooker,[3] it was seen that there was no justification for this distribution of the two substituting groups. They showed, in their very careful research, that retene is a methylisopropylphenanthrene but they were not able to determine the position of the two groups. They state positively that they did not prove that the groups are in the para (5,8-) position or even that they are both united to the same benzene nucleus. They thought one group to be in the ortho (8-) position, however. The diphenyleneketone-dicarboxylic acid (V) obtained from retene does not yield an anhydride easily. When this acid is heated with potassium hydroxide it yields a diphenyltricarboxylic acid. On page 114, they state that this acid yields a fluorescein, thus showing that the groups are in the ortho position. On

[1] This Journal, 30, 1244 (1908).

[2] *Ibid.*, 32, 219 (1910).

[3] *Ann.*, 229, 114 (1885).

page 161, they describe the same acid as not changing in any way *even at* 270°. They, as well as nearly all of those who used this argument, evidently overlooked this contradiction. Even if an acid (VI) not splitting out water were formed quantitatively, it would still be possible that the groups were in the ortho position originally. Failure to consider the possibility of isomeric acids has led to uncertainty in other cases in assigning structural formulas to derivatives of diphenyl, diphenyleneketone and other substances of this kind. Since there are *twenty-eight* isomers possible, considering only two rings, in the case of retene, it is evident that the formula given in the literature has no value. The idea of getting substances of known structure from this hydrocarbon was therefore abandoned for a time.

A little later it was pointed out by Fortner[1] that the formula of retene must be incorrect. He synthesized a 2-diphenyleneketonecarboxylic acid which was found to be identical with one obtained from retene by Bamberger and Hooker. This showed that one of the groups in retene must be in position 2- but he was not able to determine which one.

Schultze[2] in working on resin-oils, showed that they contain hydrogenated retenes. He showed that these could be transformed into retene and also that they could be oxidized to *1,2,4-benzenetricarboxylic acid.* This observation proves that the two groups cannot be on the same benzene ring. The same observation had also been made by earlier observers, only one might question whether their compounds were pure enough to be used for work on the constitution of retene.

Lux[3] also investigated the constitution of retene. By fusion of reteneketone with potassium hydroxide, he obtained two methylisopropyldiphenylcarboxylic acids. One of these acids did not esterify easily and he concluded that it must contain two substituting groups in the ortho positions to the carboxyl group. This was used to show that in retene one group must be in the meta position (8-) compared with the diphenyl. He was not able to determine whether this group was methyl or isopropyl. As a result of the work of Fortner, Schultze, Lux and others, it follows that the formula (I) of Bamberger and Hooker cannot be correct but that retene probably has a structure represented either by formula II or III.

In addition to these, Easterfield and Bagley have advocated the formula with the methyl group in position 8- and the isopropyl group in position 6-. It will be shown in the latter part of this paper in discussing the structure of abietic acid (VII), that some of the evidence upon which they base this formula is really the strongest evidence which can be cited against it.

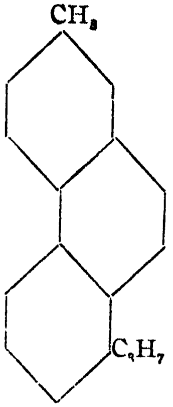
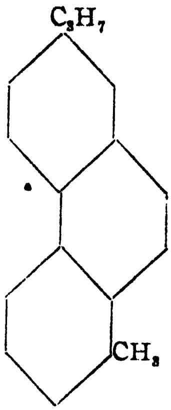
I.



II.

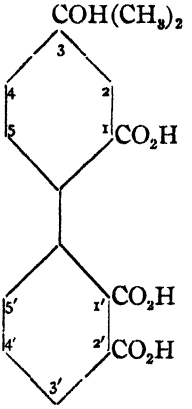


III.

In our study of the oxidation of organic substances in pyridine solution in this laboratory, we obtained compounds which give a perfectly satisfactory solution of this problem—the properties of the oxyisopropyldiphenyltricarboxylic acid obtained in the following manner showing the position of the methyl group in retene.

Ten grams of retenequinone are dissolved in 50 cc. of pyridine and 25 cc. of water in a three-liter flask, provided with a reflux condenser. The flask is heated on the water bath and in the course of half an hour 60 grams of finely powdered potassium permanganate are added in about six portions. The flask is shaken vigorously during the process and more water is added, as needed, to keep the contents in a pasty condition. The total quantity of water present at the end of the experiment should be about 100 cc. The heating and shaking were continued until the permanganate was all reduced. The whole operation required about one hour. The pyridine was then recovered by distilling it with a current of steam until the odor had disappeared. The oxides of manganese were then removed by filtration and 1.1 grams of unchanged retenequinone recovered from them. The warm filtrate was then oxidized with 10 grams of potassium permanganate to complete the process. When the color had disappeared, the solution was filtered, made nearly neutral with sulphuric acid and concentrated to a small bulk to remove the potassium sulphate. It was then acidified and extracted with ether. On distilling off the ether, a mixture of acids was left in the form of a sirup. After the addition of a small quantity of water, the solution was boiled *in vacuo* until the odor of ether disappeared. It was then allowed to evaporate spontaneously nearly to dryness. On taking up the acids with a little warm water, one sparingly soluble acid could be separated from the other very soluble acids. After crystallizing from water, 2.2 grams were obtained.

The acid titrated for a tribasic acid with a molecular weight of 345. The theory for an hydroxyisopropyldiphenyltricarboxylic acid (IV) is 344.

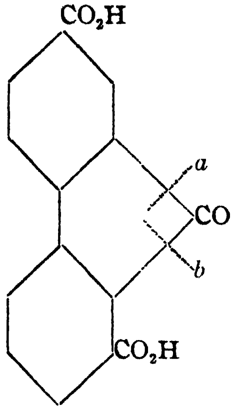


IV.

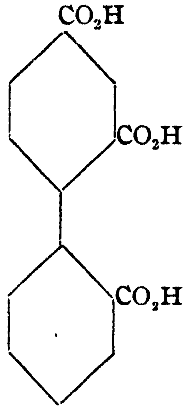
The acid loses water easily upon heating, leaving a residue which is still soluble in sodium carbonate. This shows the acid to be tribasic. The formation from retenequinone shows the position of groups 1- and 1′-. The formation of water on heating shows another carboxyl group in an adjacent ortho position (2′-). As the isopropyl residue remains in the compound, it is certain that group 2′- must have come from the methyl group. It follows from this that the methyl group must be in position 8- in retene. This excludes formula II and shows that formula III for an 8-methyl-2-isopropylphenanthrene must represent the structure of retene.

This experiment also yields other important evidence. On further oxidation the oxyisopropyl acid (IV) yields the corresponding tetrabasic acid which is easily soluble in water and gives diphenyl for the hydrocarbon. This tetrabasic acid, on heating, gave off water but the residue dissolved in sodium carbonate with effervescence. The acid, therefore, does not contain a carboxyl group in position 2 (formula IV). Also, a small quantity of *1,2,3-benzenetricarboxylic acid* was obtained—proving that in retene the groups must be united to different rings. These products alone are sufficient to determine the general structure of retene—the only point left open in formula III being whether the isopropyl group is in position 2, 3 or 4. There can be no doubt that the other acids which are formed in this one oxidation experiment will enable us to tell which of these three possibilities is the true one.

However, it was thought easier to oxidize the diphenyleneketone dicarboxylic acid (V) which Bamberger and Hooker obtained from retene by oxidation.



V.



VI.

Bamberger and Hooker state that this acid is oxidized to oxalic acid by potassium permanganate. This view is misleading, however, as comparatively small quantities of oxalic acid are formed. It has been shown that acids of this type are oxidized very readily to the corresponding benzenepolycarboxylic acids.[1] One would expect this particular acid to break up at *a* and *b*, thus yielding *two* isomeric benzenetricarboxylic acids.

Accordingly, one gram of this yellow ketonic acid was oxidized with potassium permanganate in the usual way. After filtering off the oxides of manganese, the solution was concentrated, acidified and extracted with ether. The sirupy solution of acids was heated in an evaporating dish over the water bath to expel the last traces of ether. Fuming nitric acid and a crystal of manganese nitrate were then added. Brisk effervescence, due to the oxidation of oxalic acid and probably some —$CO.CO_2H$ groups, took place at once and a white solid acid separated. The solution was evaporated to dryness and the acid washed with fuming nitric acid and then recrystallized from water. The acid separated in clear massive crystals, which are characteristic of 1,2,3-benzenetricarboxylic acid. It titrated for a molecular weight of 246 and lost 14.45 per cent. of water at 100°. Theory for 1,2,3-$C_6H_3(CO_2H)_3.2H_2O$; $M = 246$, $H_2O = 14.63$ per cent. The water of crystallization serves to distinguish it from the isomeric 1,2,4-benzenetricarboxylic acid which occurs in the filtrate and separates at ordinary temperatures without water of crystallization. The crystals of the latter acid are also quite different so there was no trouble in recognizing it. Both gave excellent yields of benzene for the hydrocarbon.

The isolation of both these acids limits the structure of retene, at once, to one group in position 8- and the other group in either position 2- or

---

[1] THIS JOURNAL, 32, 220 (1910).

3-. It also excludes Bamberger and Hooker's formula, which would necessitate the formation of 1,2,3,4-benzenetetracarboxylic acid and phthalic acid. Taken in connection with the above oxidation in pyridine solution the only question left open is whether the isopropyl group in formula III is in position 2- or 3-.

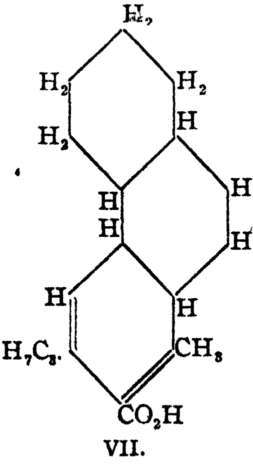
The oxidation of the diphenyleneketonedicarboxylic acid (V) was also effected in the following way. Heating this acid with potassium hydroxide should lead to the formation of the acid represented by formula VI, the ring breaking at *b*. The acid obtained in this way did not split out water upon heating, confirming the view that the statement made by Bamberger and Hooker on page 161 in their article is correct and that the structure they suggest on page 114 is incorrect. This 1,3,2'-diphenyltricarboxylic acid was then dissolved in 5 parts of fuming nitric acid, the solution being boiled ten minutes in the water bath. It was then evaporated to dryness in a casserole, taken up in hot water and reduced with sodium amalgam. The oxidation was then carried on exactly as in the preceding experiment, except that concentrated nitric acid was used instead of fuming acid in the final treatment with nitric acid and manganese nitrate. This avoids the danger of getting nitro acids. As expected, this experiment gave a small quantity of meta-phthalic acid and a large quantity of 1,2,4-benzenetricarboxylic acid. The latter acid contained no water of crystallization, titrated for a molecular weight of 212 and gave a good yield of benzene for the hydrocarbon. These results are in thorough accord with those obtained by the direct oxidation of the yellow ketonic acid (V).

On oxidizing reteneketone, Bamberger and Hooker obtained a mixture of the diphenyleneketonedicarboxylic acid (V) and the corresponding hydroxyisopropyldiphenyleneketonemonocarboxylic acid. We have shown that this mixture can be used in the above experiments instead of the pure dibasic acid—thus avoiding a very tedious process of purification. As there is no danger of ambiguous results, this mixture was also used in the following experiment: It was heated with potassium hydroxide at 218° to break up the ketone ring and form the corresponding acid derivatives of diphenyl. The resulting acids were reduced with hydriodic acid at 200° in the hope of reducing the hydroxyisopropyl group to the isopropyl group. The hydrocarbon was then prepared in the usual way. One would expect the oil thus obtained to be a mixture of diphenyl (from acid V), and of isopropyldiphenyl. This mixture was oxidized in pyridine solution with potassium permanganate exactly in the way described above for retenequinone. After the oxides of manganese and neutral matter had been removed, the alkaline solution was acidified and extracted with ether. The acid thus obtained was 3-diphenylcarboxylic acid. This completes the evidence for the constitution of retene by showing that the isopropyl group is in position 2- as represented in formula III. As this evidence, based especially on the formation of the two isomeric benzenetricarboxylic acids, 3-hydroxyisopropyl-1,1',2'-diphenyltricarboxylic acid and 3-diphenylcarboxylic acid *directly from retene*, is independent of all previous work we now have very strong evidence that the above structure must be correct.

The constitution of retene having been established, it is now an easy matter to correct the various structural formulas of the retene derivatives which appear in the literature. This includes compounds of diphenyl, diphenyleneketone, fluorene, reteneketone, retenequinone, etc.

Many important natural products are hydrogenated derivatives of retene. This is true especially of resin and resin oil derived from the *Coniferae* as is shown by many investigations, among which may be mentioned that of Schultze.[1] The mineral resin fichtelite, $C_{18}H_{32}$, is a completely reduced retene. It is therefore tetradecahydro-8-methyl-2-isopropylphenanthrene. The resin left from the distillation of turpentine is said to consist very largely of abietic acid. This acid is claimed to be a decahydroretenecarboxylic acid $C_{18}H_{27}.CO_2H$ and it is therefore not surprising that its hydrocarbon, $C_{18}H_{28}$ should occur in resin oil.

That abietic acid has the above constitution was apparently shown by Easterfield and Bagley[2] who succeeded in converting it into retene and also into dehydrofichtelite $C_{18}H_{30}$. As the acid has a low esterification velocity, they conclude that it is a diortho-substitution product. The formula of Bamberger and Hooker (I) for retene does not allow such a structure and they consider it incorrect in consequence. They then change the isopropyl group to position 6- and write the formula as follows (VII).



VII.

---

[1] *Ann.*, 359, 129 (1908).

[2] *J. Chem. Soc.*, 85, 1238 (1904).

Their formula would make retene an 8-methyl-6-isopropylphenanthrene. They offer no better evidence for their formula than Bamberger and Hooker did for formula I. They state that the formula is in accordance with the oxidation products, 1,2,4-benzenetricarboxylic- and metaphthalic acids! The very formation of these acids, however, is conclusive evidence against the formula, for such a compound would not yield the above acids. Their assumption is also shown to be untenable by the work described in this paper. It does explain the low esterification velocity of the acid, but many other arrangements would do just as well.

It may be pointed out that the formula (III), which has now been proved for retene, has *one* position (1-) diortho-substituted and if abietic acid is really a carboxyl derivative, the acid group might be in this position. The very extensive literature is so contradictory that one can not rely on it to decide this point. Some consider the abietic acid to be a dihydroxy derivative and others even question the composition, $C_{19}H_{28}O_2$, of the acid.

The wide bearing of the work, on retene, on natural products is still further shown by the suggestion of Neuberg and Rauchwerger that cholesterol is related to abietic acid and may therefore contain a reduced retene nucleus.

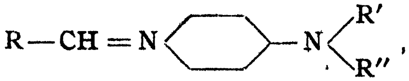
THE COLORED SALTS OF SCHIFF'S BASES.

III. THE SALTS OF BASES FORMED BY CONDENSING *m*-AMINODIMETHYLANILINE AND *m*-AMINODIETHYLANILINE WITH AROMATIC ALDEHYDES.

By F. J. Moore.

Received January 19, 1910.

It has already been shown in previous papers[1] that benzylidene compounds of the general type,



when treated with acids in non-aqueous solvents, add successively two molecules of the latter, and that the salts containing one molecule of acid differ markedly in color from those containing two molecules. The former are, for the most part, dark red, while the latter are light yellow, the free bases themselves varying from a light cream color to orange. For this behavior three possible explanations have been suggested. For a detailed discussion of these, the reader must be referred to the papers mentioned. Here it will be sufficient to sum them up briefly as follows:

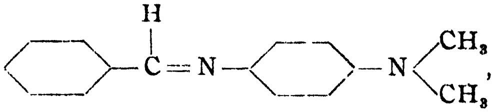
The first ascribes the difference in the color of the salts to the position of that nitrogen atom selected by the first molecule of acid. The second assigns to the dark-colored salts a quinoid constitution, regarding the compounds of lighter color as benzoid. The third assumes the potential existence of stereoisomeric red and yellow bases and salts, whose relationship to each other is akin, perhaps, to that of the isomeric unsymmetrical oximes.

---

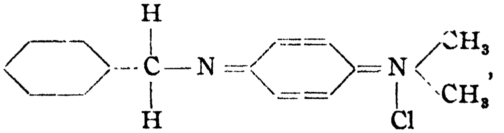
[1] This Journal, 30, 394 and 1001.

The work described in the present paper was undertaken with the intention of testing the second of these explanations, which regards the dark-colored substances as quinoid. In accordance with this hypothesis, the addition of hydrochloric acid to benzylidene-*p*-aminodimethylaniline, for example, would cause transformations such as are illustrated by the following series of formulae:

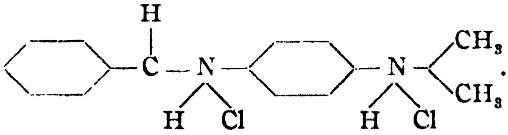
(1)



(2)



(3)



A convenient method of testing this hypothesis would consist in preparing analogous compounds which, from their structure, could not readily assume a quinoid constitution, and testing the results of salt formation in these cases. Now it is well-known that *p*-quinones form with considerable readiness, whereas *o*-quinones are more difficult to prepare, and *m*-quinoid substances are not known with certainty.[1] Applying this reasoning to the case in hand, it might be argued that the bases previously used in the course of this investigation might well form quinoid salts, since they all had their two nitrogen atoms in *p*-position to each other. It might, however, be confidently expected that the analogous *m*-compounds could not do this. Should these bases, when prepared, show a behavior with acids which was different from that of the *p*-compounds, then it might well be concluded that the dark-colored salts of the latter were quinoid. Should the *m*-compounds, on the other hand, show the same behavior as the *p*-compounds, then one of two possible conclusions might be drawn: either that the dark-colored salts of the *p*-compounds were not quinoid, or else that *m*-quinones may be formed more readily than any other evidence has thus far led us to believe.

---

[1] Compare R. Meyer, *Ber.*, 41, 2437; Zincke and Schwabe, *Ber.*, 42, 797; R. Meyer and Desamari, *Ber.*, 42, 2809.

The compounds first selected for the experimental investigation were the products formed by condensing *m*-aminodimethylaniline with aromatic aldehydes. The reaction takes place readily and smoothly. When the products were treated with hydrochloric acid in ethereal or benzene solution, all the salts formed proved to be light in color, the shade not being markedly different, whether base or acid was in excess. The greatest difference of this kind was shown by the condensation product with cinnamic aldehyde, which gave a decidedly redder precipitate when acid was in excess, than under the reverse conditions. It will be noticed that this behavior was entirely different from that of the corresponding *p*-compounds. On its face, this would seem to indicate that the dark-colored salts of the latter were quinoid. Unfortunately this argument is a good deal weakened by the curious physical properties of the bases themselves.

While the *p*-compounds crystallize beautifully from alcohol and other organic solvents, and have sharp melting points which make them useful for the identification of aldehydes, the condensation products of *m*-aminodimethylaniline with aldehydes have properties, which are the reverse of all this. They are typically amorphous, they crystallize from no solvent yet tried, and they have no melting point, but soften gradually on heating. They are, for the most part, very soluble in benzene, and on evaporation of this solvent, they are left as transparent resins which show no signs of crystallization even after months of standing. The products form readily when aldehyde and amine are mixed, and the yield is good. Side-reactions do not seem to take place, and when pains are taken to purify the products as far as possible, the analytical results agree well with the formulae derived from the method of preparation. Apparently then, the properties just described must belong to the compounds as such, although, of course, the usual criteria of purity are lacking. These properties would seem to indicate that the substances concerned were polymers, and if this were the case, the possibilities of constitution which have been thus far discussed might have little bearing. It seemed desirable to test this point by means of molecular weight determinations. Freezing-point measurements were therefore attempted in both benzene and diphenylamine. The substance chiefly studied was benzylidene-*m*-aminodimethylaniline, because it was believed that the sample used was purer, perhaps, than any of the other bases. A series of tests was, however, made with each of the other compounds. The results were discordant and unsatisfactory, the numbers obtained sometimes differing among themselves by a figure corresponding to a whole unit formula. Nevertheless the sum total of the results would seem to show that the bases were not high polymers. Speaking generally they indicate that in 0.5 per cent. solution, the bases were bimolecular. The association seemed to increase with increasing concentration, and in a 2 per cent. solution, the compounds appeared to have a molecular weight three or four times that represented by the simple formula. These results cannot be called satisfactory or conclusive, but are, perhaps, as much as can be expected from materials whose purity and homogeneity is open to so much question.

Since in any case the results above described gave no satisfactory solution to the original problem, *m*-aminodiethylaniline was prepared and condensed with five of the more common aldehydes. These compounds, in their turn, showed the same properties which have been already described as characteristic of the methyl compounds. They, too, are amorphous waxes or gums, and their salts are, for the most part, of light color, whether one or more molecules of acid are added.

Although both these bases have proved a disappointment so far as that problem is concerned for the solution of which they were originally prepared, yet their uniformly amorphous character when compared with the crystalline nature of the isomeric *p*-compounds suggests that their study might throw some light upon the fundamental differences which exist between the *m*- and *p*- relationships in di-substituted benzene derivatives. It is hoped to extend this study further in the future.

Experimental Part.

The *m*-aminodimethylaniline used in this investigation was prepared by the method of Groll[1] from dimethylaniline. The directions are easy to follow, and the product obtained is of satisfactory purity. When distilled in hydrogen, it boils with perfect constancy at 267° to almost the last drop.

From the literature, it is easy to get the impression that the aminodimethylanilines are unstable compounds. This is not the case, but they are extremely sensitive to the oxygen of the air. Indeed they turn black and grow tarry even on standing a few days in a well-stoppered bottle. If, however, they are distilled in hydrogen, and then the connections are hermetically sealed without allowing any access of air, no deterioration takes place. Samples which were treated in this way have been preserved in this laboratory for more than two years, and show no signs of change.

Benzylidene - m - aminodimethylaniline. — Molecular quantities of *m*-aminodimethylaniline and benzaldehyde were mixed. Condensation took place with a slight evolution of heat in the course of a few minutes, the mass becoming thick and pasty. To free the product from any possible excess of the amine or aldehyde, it was warmed several times with small portions of dilute alcohol (in which it is not very soluble), the pasty mass being constantly stirred to bring all parts of it into contact with the solvent. During this treatment, the substance assumes the consistency of a thick paste which can be drawn out like molasses candy into long golden-yellow strings. After several treatments of this kind, the substance grows hard and brittle on cooling. When this point had been reached, it was pulverized and washed with cold dilute alcohol. Finally, enough cold 95 per cent. alcohol was employed to bring the residue into solution, and this solution was poured into a large quantity of cold water. This causes a milky turbidity, but if a little sodium chloride solution is added, the substance is precipitated in flocks, which may then be rapidly filtered by suction and washed repeatedly with cold water. This latter method of purification was twice repeated, and the product finally dried in vacuum. It was now a light yellow mass which retained hardly any odor of benzaldehyde, and when pulverized was extremely electric. No crystalline form could be observed in this product, and all attempts to find a solvent from which it would crystallize have proved fruitless. Nevertheless the following results of analysis seem to show that the substance was essentially pure benzylidene-*m*-aminodimethylaniline.

Found:	79.97;	7.20;	12.69.

Condensation Products with Other Aldehydes.—*m*-Aminodimethylaniline was also condensed with anisaldehyde, cinnamic aldehyde, and piperonal. All the products had essentially the same properties as that just described. For this reason, the details need not be repeated. Purification was also carried out in the same manner where this was possible, but the method of dissolving in alcohol and precipitating by water did not work well in the cases of the cinnamic aldehyde and piperonal compounds. It is therefore probable that these compounds were not as pure as the others. This is also borne out by the results of analysis. Only nitrogen determinations were made in these cases.

Anisylidene-m-*aminodimethylaniline*: Calculated for $C_{16}H_{11}ON_2$, N 11.05; found, 10.91.

Cinnamidene-m-*aminodimethylaniline*: Calculated for $C_{17}H_{18}N_2$, N 11.23; found, 9.96.

Piperonylidene-m-*aminodimethylaniline*: Calculated for $C_{16}H_{16}O_2N_2$, N 10.45; found, 9.04.

Derivatives of m-*Aminodiethylaniline.*—The *m*-aminodiethylaniline required was prepared essentially according to the suggestions of Groll[1] by nitrating diethylaniline and reducing the *m*-nitro compound. Groll's directions for the nitration and separation of the *m*- and *p*-products can hardly be improved. From reading his article, however, one gets the idea that the *m*-nitro compound can be distilled at ordinary pressure. Attempts made to do so in this laboratory yielded a product much contaminated by water and some ill-smelling substance whose odor resembled that of pyridine. This nitro compound can however be obtained in a high state of purity by distilling with steam. At 100° this process is very slow and tedious, and the quantities of water required are so large as to render the subsequent ethering-out very laborious. Much better results are obtained when the flask containing the nitro compound is placed in an oil bath heated to 160° (thermometer in the bath) and superheated steam then blown through. In this way, no water condenses in the distilling flask, and a liberal quantity of very pure oil distils over rapidly. Small amounts of this nitro compound can be conveniently identified by the precipitate obtained at once when it is treated with picric acid in alcoholic solution. After a single crystallization from alcohol, this picrate melts at 138° (uncorrected).

---

[1] *Loc. cit.*

Reduction to the amino compound proceeds very smoothly under the influence of tin and hydrochloric acid. The most convenient method of isolation is to pour the hot reduction mixture directly into an excess of concentrated caustic soda solution, warm a few minutes, cool with an equal quantity of ice, and shake out with ether. A second treatment with ether is superfluous. In this way, 75 grams nitro compound yielded 50 grams amine which, when distilled in hydrogen, boiled constantly at 277°. The freshly distilled base is as nearly colorless as freshly distilled aniline, and consequently somewhat purer than that described by Groll. Like other substances of its class it is very sensitive to the air, rapidly turning brown. Portions of it which are not intended for immediate use should therefore be at once sealed up in an atmosphere of indifferent gas. When an alcoholic solution of the base is mixed with picric acid, no precipitate forms at once, but after standing for some time, beautiful yellow prisms separate. These can be washed repeatedly with cold alcohol, and then recrystallized from the same boiling solvent. They then melt sharply at 152°.

Condensation Products with Aldehydes.—These compounds were prepared in the same manner as the analogous methyl compounds. A general account of their physical properties has already been given in the earlier portion of this paper. These properties made it so evident that no assistance could be obtained from them, in solving the question at issue, that no thorough study was made of them, and no analyses carried out. A brief account of their appearance and the color of their addition products with hydrochloric acid follows.

The condensation products with benzaldehyde and anisaldehyde are stiff, golden yellow gums. When they are dissolved in ether, and an ethereal solution of hydrochloric acid is added, the precipitate first thrown down is pale yellow. This becomes practically white when an excess of the acid is added.

The compound formed with cinnamic aldehyde is a brick-red pasty mass. It also is soluble in ether, and from this solution hydrochloric acid precipitates a flocky red salt.

The condensation product with piperonal is a greenish yellow slime. When hydrochloric acid is added to its solution in dry ether, the precipitate first formed is pale yellow. A little more acid changes this color to a light red, and an excess to a bright lemon-yellow.

The compound formed with vanillin is a dark, blood-red, transparent jelly. Hydrochloric acid precipitates yellow salts.

Summary.

The salts of bases formed by condensing *m*-aminodimethylaniline and *m*-aminodiethylaniline with aldehydes do not show the same peculiarities of color as the corresponding salts of the *p*-compounds.

From this the conclusion might be drawn that the dark-colored salts of the latter were quinoid, but the force of this argument is a good deal weakened by the probability that these *m*-bases are polymers.

The amorphous character of these compounds (perhaps due to polymerization) in contrast to the crystalline nature of the *p*-compounds suggests applications to the benzene problem which are worthy of future study.

The thanks of the writer are due to Mr. E. G. Genoud for much valuable assistance during the earlier portions of this work.

MASS. INST. TECHNOLOGY, BOSTON, MASS.

THE ACTION OF MAGNESIUM UPON THE VAPORS OF ORGANIC COMPOUNDS.

BY EDWARD H. KEISER AND LEROY MCMASTER.

Received January 18, 1910.

In 1894 Edward H. Keiser and M. B. Breed[1] studied the action of metallic magnesium upon the vapors of some of the aliphatic alcohols and found that when the metal is heated in a tube through which the vapor of the alcohol is passing it soon begins to glow and after the action has ceased and the tube allowed to cool, a black residue is left. This residue when put into water evolves a gas slowly and on the addition of a few drops of ammonium chloride a more rapid evolution of gas is obtained. It was shown that the gas thus given off consisted of hydrogen mixed with small quantities of allylene.

In a subsequent paper by Edward H. Keiser[2] the work was continued, other alcohols and acetone were subjected to the action of magnesium, and it was shown that in every case the black residue gave off allylene when treated with water. The best yield of allylene was obtained from the black mass formed by the action of magnesium upon acetone. It was also shown that when magnesium is heated in an atmosphere free from hydrogen, as for instance, in carbon monoxide and carbon dioxide, a very hard compact black mass is obtained which gives only small quantities of allylene on treatment with water. The conclusion was, therefore, drawn that a magnesium compound of allylene was probably present in the black residue.

---

[1] *J. Franklin Inst.*, Dec., 1894.

[2] *Am. Chem. J.*, 18, 328.

We have now endeavored to determine whether a magnesium compound of allylene or simply a carbide of magnesium is present in the black residue. In the earlier experiments several of the aliphatic alcohols, allyl alcohol and acetone had been acted upon by the magnesium; we now extended the work so as to include other classes of compounds such as paraffin and aromatic hydrocarbons, aliphatic acids and esters, aromatic alcohols, halogen derivatives, acetylene, cyanogen, etc.

The method of operating was the same as before, the metal in an iron boat was placed in a combustion tube of glass, the tube was heated in a small furnace and the organic compound was passed through the tube in the form of vapor. After the action was over the black magnesium residue was allowed to cool off in the vapor. The black residue was then put into a dry evolution flask provided with a separatory funnel and water containing a few drops of ammonium chloride was allowed to drop upon it. The gases evolved were passed into an ammoniacal solution of silver nitrate. The silver precipitates thus obtained were analyzed. The following table (see p. 390) contains the results of these analyses.

These results show that in every case when magnesium is heated in the vapor of a compound containing hydrogen the unsaturated hydrocarbon evolved from the black residue is chiefly allylene. When hydrogen is absent, as in the cases of cyanogen and carbon monoxide a very poor yield of unsaturated hydrocarbon is obtained, four to five times as much of the black magnesium residue must be used in order to obtain sufficient of the silver precipitate for analysis. The analytical results show that even in these cases the gas evolved is not pure acetylene but contains some allylene. Thus from cyanogen the silver precipitate was found to contain but 82.95 and 82.72 per cent. of metal whereas pure silver acetylide contains 89.9 per cent.; and in the case of carbon monoxide the silver precipitate gave 78 per cent. of silver. These low results indicate a mixture of allylene and acetylene and at first thought it would appear that a carbide of magnesium is formed in all these experiments and that the allylene is formed by the action of water upon this carbide. This conclusion would be justified were it not for the fact, noted in the earlier paper, that magnesium powder contains hydrogen, either as occluded hydrogen, or hydroxide or both. This has been proved by burning weighed amounts of magnesium powder and weighing the water formed.

The average result of two combustions of magnesium powder, previously dried for several hours at 120° in an air bath, gave 0.065 per cent. of hydrogen.

CO + N_2 + HCl	0.0550	0.0547	74.80
Calculated for silver allylide, AgC_3H_3			73.45

This fact of the presence of hydrogen in the magnesium and the other fact that only a very small amount of the unsaturated hydrocarbons is obtained from carbon compounds containing no hydrogen led us to conclude that magnesium allylide is present in the black residue. There is undoubtedly a tendency on the part of magnesium, under the conditions of our experiments, to combine with carbon and hydrogen to form magnesium allylide and it is this compound which with water evolves allylene. This is shown clearly in the case of the experiments with acetylene. When magnesium powder is heated in this gas a black residue is obtained which with water gives off both allylene and acetylene. Here the conditions were favorable for the formation of only a carbide, as MgC_2, yet the gas given off consists of both hydrocarbons. Further, when carbon monoxide, diluted with nitrogen to make the action less violent, was acted upon by magnesium, the black residue gave very little silver precipitate, but when hydrochloric acid gas was added to the mixed gases then a good yield of unsaturated hydrocarbon was obtained and the analysis of the silver precipitate indicated nearly pure allylene. We conclude, therefore, that it is magnesium allylide that gives the allylene and not a carbide.

CHEMICAL LABORATORY, WASHINGTON UNIVERSITY,
ST. LOUIS, MO

STUDIES IN THE ACTION OF HEAT ON MILK.[1]

BY R R. RENSHAW AND F. C WARE.

Received January 11, 1910.

A number of experimenters[2] have noticed that when milk is heated, the lactose apparently diminishes in quantity. The subject, however, has not been systematically investigated.

Richmond[3] first called attention to the fact that the specific rotatory power of lactose in milk materially diminished on heating, but that the reducing power decreased only slightly. Later he and Boseley[4] determined lactose in samples heated for $1^1/_2$ to 3 hours at 100° and found that there was a decrease of from 8.8 per cent. to 23 per cent. of the sugar as measured by the optical method. In another series where sugar was determined gravimetrically, no change was noticed. They offered the suggestion that this may be due to the formation of caramel, since the rotatory power decreased roughly in proportion to the increase of yellow color in the milk.

It did not seem to the present authors that caramelization could be the primary cause of the difference in the optical and gravimetric determinations, since the rotatory and reducing power should decrease nearly proportionally, due to the relatively large molecule of the caramel compared to that of lactose. It was for the purpose of investigating this that the following experiments were undertaken. We were particularly interested to find out the character and extent of the change taking place at the temperatures which might be used in pasteurization.

A number of possible causes for the change in rotatory power of the milk serum presented themselves among which may be mentioned changes producing soluble *l*-rotatory glycerophosphates,[1] or small amounts of a highly *l*-rotatory amino acid, not precipitated by the clarifying agents used. In order to test these, the sugar was determined by both methods, as well as total phosphorus and total nitrogen in the protein-free serum, on samples of milk heated different lengths of time up as high as 80°. A rapid decrease of sugar was noticed, but strange to say nearly identical results were obtained by each method, and in all subsequent work concordant results were obtained where great care was used in maintaining uniform conditions, particularly as to temperature of pipetting samples,[2] complete washing of the asbestos filter, etc. With such results from the preliminary experiments it was thought not necessary to consider phosphorus and nitrogen determinations.

---

[1] Submitted by F. C. Ware, in partial fulfilment of the requirement for the degree of Master of Arts at Wesleyan University, June, 1908. The experimental work was carried on in the Chemical Laboratory, Stamford High School, Stamford, Conn.

We next took up a study of the behavior of lactose in a solution which contained approximately the same active mass of hydroxyl ions that occur in milk, in order to see if the alkaline salts were instrumental in the decomposition. Owing to the great complexity of milk as a solution, with its varying amounts of di- and triatomic acids and bases, each with a different temperature coefficient of ionization, and to the incalculable chemical changes caused by heat, it is impossible to compute ionic concentrations. Practically, however, an approximation could be obtained easily, by making a solution containing equivalent percentages of the principal electrolytes found in milk, with the understanding that precipitation of solids and evolution of carbon dioxide would occur. For this purpose 1 gram each of hydrochloric and citric acids,[3] 2.42 grams phosphoric acid, and calcium carbonate containing 1.9 grams of calcium oxide, were mixed with water and the solution neutralized to phenolphthalein with 0.1 *N* sodium hydroxide and 148 cc. (alkalinity × 10) in excess added. In this, 4.87 grams of lactose were dissolved and the whole made up to a liter, giving a solution containing one-tenth of the percentage of sugar that was found in the milk we were working with. No change in sugar content was noticed after heating this for two hours and a half at 85°. This solution, containing approximately the same amounts and similar kinds of positive and negative elements or radicles as occur in milk, except, of course, that all were in inorganic combination, should afford as high, if not a higher, hydroxyl ion concentration than the milk. It seemed then that the salts had no effect on the sugar at this temperature.

Series of tests were next run on milk heated to 60, 70, 80, and 85°. Three sets of samples were made up for each temperature from the same specimen. One of pure milk, the second containing formaldehyde, 1 : 2500, and the third the same, 1 : 20000. The aldehyde was used in these two concentrations in the hope of distinguishing between bacterial and enzymatic action.[1]

---

[1] Bordas and Raczkowski (*Ann. chem. anal.*, 8, 168 (1903)) have shown that when milk is heated the lecithins are decomposed.

[2] It was noticed that temperature differences materially affected results. The analytical work was done in a room fitted up with a constant temperature regulator.

For sugar, the Wiley and Erwell optical and the Defren gravimetric methods were used. The acidity was determined with phenolphthalein without the removal of carbon dioxide and is expressed below in cc. of 0.1 *N* sodium hydroxide per 100 cc. milk. Lacmoid was used for alkalinity. It also is expressed in cc. 0.1 *N* solution per 100 cc. milk.

The presence of a sediment containing calcium phosphate was confirmed in the pasteurized milk.

The sugar, acidity and alkalinity were determined immediately after cooling the sample. The milk used in the 70 and 80° tests was of the same lot, from a mixed herd, and was about five hours old at the beginning of the 70° test. That for the 80° test stood about four hours longer in a good refrigerator. The tests at 60 and 85° were run about a month later on milk from the same dairy and at about the same length of time after milking.

The results for 60 and 80° are given below in detail:

RESULTS ON MILK HEATED AT 60°.—LACTOSE.

[1] Price (*Abs. U. S. Hyg. Lab., Bull.* 41, 379) has shown that many enzymes can withstand formaldehyde 1 : 20000, while the growth of the more common bacteria is prevented. A strength of 1 : 2500 stops the action of most enzymes.

[2] This does not include the time of heating necessary to bring the milk up to the required temperature in the thermostat but means 1/4 hr. at the designated temperature. For the 85° test this required 15 minutes and for the lower temperatures a somewhat shorter time.

In the series at 60°, a fairly regular and continuous decrease was noticed up to $2^1/_2$ hours in the sugar and alkalinity, while there was a corresponding increase of acidity. Practically no changes occurred in the sugar and acidity when formaldehyde was present in the proportion of 1 : 2500, and only slight changes with a strength of 1 : 20000. At 80° the changes were more rapid at the beginning and had nearly ceased by the end of the first hour. Figures obtained at 70° showed that the changes here stood intermediate between the two given. At 85° the changes went more rapidly at the beginning and were practically over after the first $^1/_2$ hour. There was neither as much decrease in sugar or alkalinity, nor as much increase in acidity, however, as in the case of the lower temperatures.

It would seem then that the major cause of the change in the sugar was bacterial or enzymatic action, for, although no very strict relationship seems to exist between the amount of acid formed and the decrease of sugar, as the following table exhibits, still, the results are in accord with Haacke's[1] observation that the amount of lactic acid found at any one time is not strictly proportional to the amount of lactose decomposed, because (probably) the lactic acid is transformed into other substances. The acid never exceeds one-third of the amount of sugar decomposed.

	60°	70°	80°.	85°
Per cent. sugar loss after $2^1/_2$ hours .	10.4	11.94	11.28	6.33

Loss of lactose in gs	0.46	0.54	0.52	0.28

It is difficult to interpret in the light of our results, the data found in the literature showing the differences in optical and gravimetric determinations for sugar in heated milk, because the temperatures used were higher (100°), and neither the history of the milk nor the details of analysis were given. We regret that time has not permitted investigating the sugar changes at 100°. It seems certain, however, that the data furnished by the difference between the optical and gravimetric methods for sugar in pasteurized milk cannot be used as confirmatory evidence of pasteurization, as has been recommended.

Theoretically, of course, very different results would be obtained from different samples of milk, due to varying amounts (as well as kinds) of inoculation, for it has been shown that the lactic acid organisms vary greatly in the extent, rapidity and persistency of their action. Tissier and Gasching[2] state that *B. acidi-paralactici* has a high order of resistance, that it works actively and vigorously, and produces mostly *d*-lactic acid. Heinemann[3] seems to have shown that ordinary *B. acidi-lactici* gives chiefly the *l*-acid, and this appears to be augmented by higher temperatures.[1]

[2] *Ann. inst. Pasteur*, 17, 540–563 (1903).

[3] *J. Biol. Chem.*, 2, 603–612 (1907).

Observations by Rullman,[2] that it requires an hour's heating at 68–69° to kill the major portion of the bacteria in milk, and by Mullen,[3] that oxidizing ferments increase in activity from 0 to 60°, and that they are still active at 80°, are noteworthy. The investigations of many others[4] support the statement that the milk ferments are not materially injured by heating at 60–65° for some time. They are weakened only at 65–70° and are finally destroyed at 70–80°.

These facts, along with the knowledge recently obtained concerning the action of Metchnikoff's *B. bulgaricus*, largely remove the cause for surprise at the large amount of sugar transformed. It has been shown that *B. bulgaricus* is universally found in milk. It works best at temperatures above 40° and under the anaerobic conditions which would prevail, at least in bottle pasteurization, and it propagates prodigiously, producing extraordinary amounts of lactic acid. It is hence not necessary to assume cytolysis, with an accompanying liberation of an intracellular enzyme having a higher thermal death-point than the organism. It is to be regretted that so little work has been done in determining the important relation between the thermal death-points of the organisms and their characteristic enzymes.

From the small differences between the results obtained by using the two strengths of formaldehyde, it would appear that one was dealing with bacterial rather than enzymatic action. This is further substantiated by the fact that it is an exceedingly difficult matter to procure lactic acid enzymes from lactic acid organisms.[5] Such small differences as are observed might be due to only partial killing of the bacteria at the lower concentration, or to a slight secretion of an extracellular enzyme.[6] The very rapid transformation of sugar into lactic acid (in one case 0.24

---

[1] These facts indicate that for very close work certainty of complete precipitation of the lactic acid by the clarifying agents is necessary if the fermentation has occurred at higher temperatures, for under these conditions equivalent amounts of *d*- and *l*-acid may not be formed.

[3] *Arch. Hyg.*, 44, 132–3 (1902).

[4] For a comprehensive review of this subject and for some original contributions, see article by Kastle and Roberts, *U. S. Hyg. Lab., Bull.* 41, 309–408 (1908).

[5] The senior author has attempted, so far unsuccessfully, to get a lactic acid enzyme from B. *acidi-lactici* in sufficient quantity to experiment with. It is hoped that this may yet be done. Herzog (*Z. physiol. Chem.*, 381 (1903)) got a very slightly active solution from this organism which would transform lactose into lactic acid in the absence of organisms.

[6] Dox, in a paper on "The Development of Catalase in Lower Fungi," read at the Boston meeting of the American Chemical Society, Dec., 1909, stated that he found a rise of temperature favored the formation of extracellular enzymes.

gram giving 0.0252 gram acid in $^1/_2$ hr.) seemed extraordinary to the authors. It has been abundantly proven, however, that there are optimum temperatures for catalyzers in general, that is, temperatures allowing a maximum in the reaction along with a minimum of destruction to the catalyzer itself.

Many instances could be cited of the extraordinary influence of rise of temperature on the reaction velocity of catalytic actions, and particularly is this true of organic catalyzers (enzymes) within narrow margins of temperature. For instance, Tammann[1] has found that the temperature coefficient for emulsin on salicin between 60 and 70° was 12.3. What is true of enzymes is also true in a degree of cells, for broadly speaking these also are catalyzers, or rather systems of catalyzers. The organisms, then, may continue very rapidly to increase in activity until finally they die in hyper-activity. With this in mind, the increased velocity of sugar decomposition as higher temperatures were used becomes clear. This affords an explanation, too, of the occasional curdling of milk on pasteurizing, and gives further reasons for using a not too highly inoculated milk in such processes.

Conclusions.

1. The alkaline salts have no effect on the lactose in milk when it is heated at 85° for some time.

2. Perfectly concordant results can be obtained by the optical and gravimetric methods for lactose in pasteurized milk.

3. Concordance between the results by the optical and gravimetric methods can not be taken, as has been suggested, as evidence that the milk has not been pasteurized.

4. In bottle pasteurization it is impossible to heat the milk quickly enough to prevent appreciable amounts of lactose being decomposed, unless the milk has a very small bacteria count.

5. Some lactic acid organism or organisms work prodigiously at a temperature of 80-85°, though for a short time. They work more slowly but for a longer time at 60°.

6. The presence of a sediment containing calcium phosphate in pasteurized milk has been confirmed.

[CONTRIBUTION FROM THE CHEMICAL LABORATORY OF MICHIGAN EXPERIMENT STATION.]

ORGANIC NITROGENOUS COMPOUNDS IN PEAT SOILS.

BY S L. JODIDI

Received January 27, 1910.

When we take into consideration that not less than one-seventh of the total area of the state of Michigan consists of swamp lands largely covered by peat and muck, which is more or less also true of New England, of the northwestern, western and middle states, and that their entire area in the Union is estimated to reach the imposing figure of 75,000,000 acres, we are impressed with the necessity of an investigation of peat soils with a view to learning as much as possible about their agricultural possibilities.

---

[1] *Z. physiol. Chem.*, 16, 323.

As far as could be learned from the literature within our reach, no systematic investigations of a similar nature have been conducted.

When we consider a soil from the standpoint of agricultural chemistry, one of the first things to demand attention is the so called tripod of agriculture. This is natural enough, since many soils are deficient in one or more of the three essential elements: potassium, phosphorus and nitrogen.

Though the atmospheric ocean surrounding the earth contains countless millions of tons of nitrogen, it is, as such, of little avail, since the plants—with the exception of the legumes—are not able to utilize the free nitrogen of the air. It is the combined nitrogen only that is of agricultural value. Besides, there are a number of processes by which the nitrogen is liberated from the nitrogenous compounds and lost as plant food. The process of combustion, the denitrification through microorganisms, and the reaction of nitrous acid upon organic nitrogenous compounds, the spontaneous decomposition of ammonium nitrite liberate[1] more or less free nitrogen.

True, some combined nitrogen in the shape of nitric acid and ammonia comes with atmospheric precipitations into the soil which is still more enriched with nitrogen through the activity of certain soil bacteria. But it is certain that, to-day, a much larger amount of nitrogen is removed from the soil than is returned to it by synthetic or other means.

In the peat bogs, nature has placed at the command of man soils with large quantities of combined nitrogen. From the data given below, it will be seen that Michigan brown peat—the most abundant type in that state—contains in round figures from 2 25 to 2.75 per cent. nitrogen in the oven-dried state. This percentage means that about four tons of nitrogen are contained in each acre-foot. Such a quantity of nitrogen, if it could be utilized, would be sufficient for continuous cropping during three-quarters of a century. As far as inorganic nitrogen is concerned, it was found that nitrates are not present in the brown peat deposits occurring in Michigan; also that the quantity of ammonia present is quite small, ranging from a few thousandths to a few hundredths of one per cent. Hence the nitrogen practically consists of organic bodies only. But of what nature are they? This question seems to be quite a complicated one when we consider that organic nitrogenous compounds exist in the shape of amines, acid amides, monamino and diamino acids, cyanides, indole derivatives, pyridine derivatives, etc., and that a good many of these bodies can be of aliphatic as well as of aromatic origin.

---

[1] O. Kellner and T. Yoshii, *Z. physiol. Chem.*, 12, 105–107 (1888).

However, contemplations of a general nature will give us some idea as to the direction in which the problem under consideration can be attacked. It must be borne in mind that peat is a decomposition product of vegetable matter. Since the bulk of nitrogen in plants is commonly made up of proteins, which are contained in all plants, it is obvious that our attention must be directed first of all to the proteins and their decomposition products. However, in order to get some general conception as to the compounds or groups of bodies that may be present in peat, we must take into consideration the processes that take place in the plants when they cease to live. It is only protein in a dry state that is of a constant nature, but when subjected in a moist state to the influence of the ubiquitous bacteria—which is the case with protein in dead plants—it soon begins to decompose. The process of decomposition splits the complicated protein molecules into a considerable number of products. The following nitrogenous decomposition products have been discovered and identified by a great number of investigators:

Ammonia,[1] leucine,[2] tyrosine,[3] aminovaleric acid,[4] indole,[5] skatole,[6] indole acetic acid,[7] indole propionic acid,[8] putrescine,[9] cadaverine,[9] ptomaines generally, and others.

The nitrogenous decomposition products furnished by boiling the proteins with acids, *e. g.*, with hydrochloric acid, are as follows:

Ammonia,[10] histidine,[11] arginine,[11] lysine,[11] diamino-acetic acid,[12] glycocoll,[13] alanine,[13] aminovaleric acid,[13] leucine,[10] tyrosine,[10] aspartic acid,[10] glutamic acid,[10] cystine,[14] phenylalanine,[13] α-pyrrolidinecarboxylic acid,[13] oxyproline and humin substances.

Since peat has its origin from gradually decayed plants, and as far as nitrogen is concerned, chiefly from decayed proteins, it follows that the

series of bodies representing the decomposition products of proteins through the action of micro-organisms is of special interest to us. However, it is not out of the question that we may find compounds present in the peat which are generally associated with the decomposition of proteins by mineral acids.

By considering the above two series of decomposition products more closely, we can readily see that the great majority of them belong to two classes of organic compounds, namely to the monamino acids—leucine, tyrosine, aminovaleric acid, aspartic and glutamic acid, etc.—and to the diamino acids—histidine, arginine, lysine and diamino acetic acid. Some of the monamino acids, *e. g.*, the aspartic and glutamic acid may originate from the amides, asparagine and glutamine, which are, as such, often contained in plants. Thus we logically come to the conclusion that the bulk of nitrogen in peat may be present in the shape of amides, monamino acids, and diamino acids.

We must not omit to mention here that it is reasonable to assume that the plants, through the decay from which the peat resulted, may have contained also nitrogenous bodies other than proteins, and further, that decomposition in nature, under the influence of its various agents, may be in some respects different from the decomposition in the laboratory of proteins proper, either by chemical means or through bacterial activity. The possible interaction of the decomposition products and the leaching in nature must also be taken into consideration. Consequently, the separation of the peat constituents into amides, diamino acids and monamino acids may not take place exactly in the same manner as it does with proteins. This should be kept in mind by viewing the data presented in Tables III and V.

The method applied for the separation of the organic nitrogenous bodies in peat soils was essentially the one employed in protein chemistry with slight modifications. A definite volume of the sulphuric acid or the hydrochloric acid extract of peat, corresponding to, say, 0.05 gram nitrogen was, after cooling, carefully neutralized with cream of magnesia, of which some excess was used. The ammonia obtained by distillation gave the amount of nitrogen corresponding to the amides present in the peat.

The residue from distillation with magnesia was dissolved in dilute sulphuric acid so as to have approximately a five per cent. acid solution, then phosphotungstic acid solution added in some excess and allowed to stand for at least twenty-four hours. The precipitate containing the diamino acids was then filtered out, washed with water containing from two and one-half to five per cent. sulphuric and the same amount of phosphotungstic acid. The filter, together with the diamino acid precipitate, was transferred to a flask and the diamino nitrogen estimated according to Kjeldahl's method.

The filtrate and washings from the diamino acids, containing the monamino acids, were filled up with distilled water to a definite volume, usually to 500 cc., of which 100 cc. or 200 cc. were oxidized by the Kjeldahl method. The amount of ammonia found by distillation and calculated to the total volume gave the percentage of nitrogen corresponding to the monamino acids.

Instead of directly determining the amount of monamino nitrogen by Kjeldahl's method, which is difficult to accomplish in an exact way, the sum of the percentages of amido nitrogen and diamino nitrogen can be subtracted from the total quantity of nitrogen extracted from the peat. The difference evidently represents the monamino nitrogen.

Experimental Part.

Prior to starting experiments with the object in view of finding out the various organic nitrogenous compounds contained in peat soils, it was thought advisable to establish their composition by elementary analysis. This was also suggested by the fact that the literature, as far as we know, contains very few complete analyses of American peat soils, at least as far as the organic constituents are concerned. The brown peat sample,[1] the analyses of which are given below, is one that is typical for Michigan. It was taken from three to four feet below the surface or about the usual water-line in that peat deposit. It was made up of fibrous remains of sedges and, in the upper layers, of small shrubs and similar plants. It represents a well-decomposed, fibrous, brown peat. In order to have the peat sample in a state suitable for analytical purposes, it was dried in an electric drying oven at a temperature of from 40 to 60°, and then put through a 20-mesh sieve.

Calculated to water-free basis, the analysis gave:

C, 55.06; H, 5.21; N, 2 74; S, 0 35; Ash, 6 62; O (by difference), 30.02.

In order to be able to separate the nitrogenous bodies present in peat soils, it was necessary first of all to find a suitable solvent for the extraction of these compounds. It was soon found that the quantity of nitrogenous substances which could be extracted with water was small. Moderately dilute hydrochloric and sulphuric acids proved to be the most suitable solvents for the purpose we had in view. Since only a small part of the peat soils could be dissolved in these acids, the suggestion was plausible that a number of factors, like the amount and concentration of the acids, temperature and duration of digestion, as well as the fineness of the samples, might have an influence upon the percentage of nitrogenous bodies that could be extracted. The experiments, the results of which are contained in Table I, have fully confirmed this supposition. Before presenting the results, however, we shall briefly describe the manner in which the peat was extracted with the various reagents. A definite amount of peat was transferred to a flask, then sulphuric or hydrochloric acid previously diluted with distilled water was added. The contents of the flask were shaken to a uniform mass, heated to the boiling point and kept boiling under a reflux condenser for a certain number of hours. Or, instead of boiling with reflux condenser, the flask containing the peat with the reagents was put into an autoclave where it was kept under a constant pressure. The boiled mass was then filtered and washed with boiling water. The peat remaining on the filter was then transferred to a flask, distilled water added, boiled for a few minutes, sucked off, washed with hot water, and these operations repeated another time. Filtrate and washings were evaporated and filled up to a definite volume, usually to 500 or 1000 cc., of which 100 or 200 cc. were taken for nitrogen determinations by the Kjeldahl method. The nitrogen found was calculated to the original volume. Results of this experiment will be found in Table I, under method (*a*).

---

[1] All of the peat samples referred to in this paper were very kindly furnished by Dr. Chas. A. Davis, of the United States Geological Survey.

Since the repeated boiling and washing with hot water, as well as the filtrations, require considerable time, this method was modified in a number of cases as follows: After digestion of the peat for a specified length of time, either under reflux condenser or in the autoclave, the flask content was cooled to room temperature and filled up to a definite volume with distilled water. After shaking, it was filtered through a dry filter, and two portions of the filtrate were taken for nitrogen estimations by Kjeldahl's method. The nitrogen thus found was calculated to the volume of the liquid minus the volume occupied by the peat. The results of this experiment will be found in Table I, under method (*b*). That these two methods differ to a degree in their results may be partly due to the high absorptive power of peat for ammonia and other nitrogenous substances.

In glancing at the table, one can see at once that the concentration of the acid and the duration of digestion have the greatest influence, whereas the quantity of the reagents used has only a slight influence upon the percentage of nitrogenous bodies that can be extracted from the peat. Thus, comparing the experiments 1 and 2, 4 and 8, 6 and 7, where, with the exception of the time of digestion, all the conditions were the same, we find that the percentage of nitrogenous substances extracted rises with increased hours of digestion. Also we notice, by comparing experiments 3 and 4, having equal hours of digestion, that, although the amount of acid used in the latter is considerably smaller than in 3, yet the percentage of extracted nitrogen is about 12 per cent. higher, showing the predominant influence of the concentration of the sulphuric acid. The same

[1] For this experiment a black peat was used which passed through a 20-mesh sieve.

[2] Black peat passing through an 80-mesh sieve.

conclusion can be drawn from experiments 1 and 3. What is true of the sulphuric acid is also true of the hydrochloric acid, which extracts about the same percentage of nitrogen as does the sulphuric acid under the same conditions. Thus experiments 4, 8 and 14, with the same or about the same hours of digestion, show that the 47 per cent. sulphuric acid extracted more nitrogen than the 38 per cent. hydrochloric acid, whereas from experiments 1 and 14 it follows that the hydrochloric acid of a higher concentration was able to extract more nitrogen than the sulphuric acid of a lower concentration.

The experiments 10 and 11 show how small an amount of nitrogenous bodies can be extracted from the brown peat by means of water. This also holds true for other types of peat, for instance, for black peat as well as for weathered brown peat.

That from a peat in a finer state of division more nitrogen can be extracted than from a coarser peat is plainly seen from experiments 12 and 13, conducted under exactly the same conditions with the exception of the fineness to which the respective peat samples were reduced. From this it follows further that the percentages of nitrogen extracted from the brown peat and given in Table I should be considered as minimum figures, since all the experiments, with the exception of 13, were made with peat which passed a 20-mesh sieve.

TABLE II.—NITROGEN EXTRACTED BY REPEATED DIGESTION WITH ACID.

But, on the other hand, even boiling for several days with quite strong acid did not dissolve out all the nitrogen contained in the peat. Since the separation of different organic, nitrogenous bodies into groups can be accomplished only in an acid solution, the question as to whether it is possible to extract all the nitrogen from peat by means of acids was of considerable importance. To definitely decide this question, a few peat samples were boiled for a number of hours with fairly strong acid, filtered and thoroughly washed with hot water. The peat was re-extracted several times, being thoroughly washed with hot water after each extraction. The filtrates and washings, after each digestion, were filled up to a definite volume and the nitrogen estimated according to Kjeldahl's method. Table II contains the results obtained through repeated digestions.

In reviewing the results of Table II, we can readily see that the total amount of nitrogen extractable from peat can be increased a few per cent. by repeated digestion, although even in the latter case it was not possible to obtain all the nitrogen in solution, 68.32 being the highest percentage of nitrogen extracted with acid. However, taking into consideration experiments 12 and 13, of Table I, as well as experiment 1 of Table II, we are justified in saying that at least 70 per cent. of the nitrogen can be obtained in solution if the digestion with acid is performed with a brown peat that has passed through an 80-mesh sieve. But the question as to whether it is possible to extract all the nitrogenous bodies from peat by digesting with acid must be answered in the negative, at least this is true under the conditions given in Tables I and II.

Separation of the Organic Nitrogenous Bodies into Different Groups.

As already mentioned, practically all the nitrogen contained in the brown peat is of organic nature. The quite small amount of ammonia present as such in the peat is, it should be remembered, also represented in the total amount of ammonia obtained by distilling the acid-treated peat with magnesium oxide. Hence, we must subtract the ammonia present as such in the fresh peat from this total amount of ammonia in order to find the ammonia corresponding to the amides only. Table III shows the percentage of the different nitrogenous groups contained in the brown peat.

From Table III it can readily be seen that the strong acid (47.5 per cent.) gave about six per cent. more nitrogen in solution than the weaker acid, and that this nitrogen was chiefly amido nitrogen, and monamino nitrogen. When we consider the nitrogen in solution as 100 and reduce to this basis the data in Table III, we get the figures contained in Table IV.

The percentage of monamino nitrogen given in this table was found by difference from one hundred. This percentage was usually higher

than the one directly found by Kjeldahlizing the filtrate from the phosphotungstic acid precipitate. For instance, in experiment 2 the percentage of monamino nitrogen directly found was only 62.83 and in experiment 3 it was 64.25 per cent. instead of 67 22 and 65.06, respectively. The chief reason why the direct determination usually gives too low a percentage of the monamino acids lies in the difficulty of a complete oxidation of the nitrogenous bodies in the presence of an excess of phosphotungstic acid.

An attempt was made to isolate in substance and, if possible, to identify the diamino and monamino acids present in the peat. For this purpose a brown peat from Chelsea, Michigan, was used, of the same type as the one previously described. Its analysis, calculated to peat free of water and ash, gave: C, 60.03; H, 5.73; N, 2.38.

With this brown peat the following experiments were made:

To 54.94 grams of air-dried peat corresponding to 50 grams of oven-dried peat, a mixture of 150 grams concentrated sulphuric acid and 300 grams of water was added, then heated to the boiling point, and kept boiling under reflux condenser for 14 hours. During the boiling, development of hydrogen sulphide was noticed. (Hydrogen sulphide was detected when another sample of peat was digested with hydrochloric acid.) The flask content was filtered, the peat remaining on the filter was transferred to a flask, boiled with water, filtered and washed with hot water. These operations were repeated three times. Filtrate and washings were evaporated, filled up to 1000 cc., and two Kjeldahl determinations made to determine the amount of extractable nitrogenous bodies. The peat extract was then treated with a hot solution of barium hydroxide in order to remove nearly all the sulphuric acid. The barium sulphate was filtered out, boiled with water three times, and each time sucked off and thoroughly washed. Filtrate and washings were somewhat concentrated and then treated with magnesium oxide on a water bath until all ammonia was removed. Barium hydroxide solution was then added in excess; the precipitate, consisting chiefly of magnesium hydroxide and barium sulphate, was filtered out and then extracted three times with hot water. Filtrate and washings were then united and sulphuric acid added in some excess to remove the baryta. The filtrate containing the organic nitrogenous bodies was treated according to the method given by A. Kossel for the separation and identification of histidine and arginine as silver compounds. The result was a negative one.

The resulting filtrate from the above procedure was acidulated with sulphuric acid and treated with hydrogen sulphide. The new precipitate consisting of barium sulphate and silver sulphide was filtered out, extracted with hot water, the filtrate and washings were somewhat concentrated and sulphuric acid was added so as to make the solution contain five per cent. It was then treated with phosphotungstic acid. A precipitate was obtained which was washed with a five per cent. sulphuric acid and then treated with barium hydroxide to remove the phosphotungstic acid. The filtrate was freed from barium by means of carbon dioxide, evaporated nearly to dryness, taken up with hot water and filtered. The filtrate, when evaporated nearly to dryness, consisted of a few drops of a brown sirup. This, treated with picric acid, gave a yellow precipitate too small in quantity for identification.

The filtrate from phosphotungstic acid precipitate, supposed to contain monamino acids, was treated with barium hydroxide to remove the phosphotungstic acid and then treated with carbon dioxide to remove the excess of barium hydroxide. The filtrate from barium carbonate showed the Millon reaction. It was natural enough to think of tyrosine. On the other hand, it must be taken into consideration that nearly all benzene derivatives in which one hydrogen atom is replaced by the hydroxyl group give the same reaction. Considering the relation of peat to protein decomposition products, phenol, ortho- or paracresol or tyrosine were possible.

On adding iron chloride to the filtrate from barium carbonate, no violet or blue color reaction was noticed. Addition of bromine water did not cause any precipitate. These two negative reactions showed that the filtrate under consideration did not contain either phenol or cresol. The non-volatility of the substance in question spoke in favor of tyrosine; however, identification of the tyrosine by means of the microscope or Piria's test could not be accomplished, since the tyrosine was not obtained in substance. This will be comprehended when we state that altogether only 0.43 gram nitrogen was originally in the shape of organic compounds, of which a part was lost through a number of operations mentioned above, and that the remaining nitrogen was very likely present in the shape of various monamino acids.

Weathered Brown Peat.

It was of interest to learn whether the peat undergoes changes, and if so of what nature, when subjected to atmospheric influences. For this purpose a sample of brown peat was taken which had been weathering for two or three years on the surface of the bog. The analysis of this peat reduced to the water-free basis, gave: C, 54.35; H, 5.56; N, 2.69; S, 0.34; ash, 3.79; oxygen (by difference), 33.27.

The nitrogen of the peat was separated into the different groups. The results are given in the table below:

TABLE V.—AMOUNT AND PERCENTAGE OF NITROGEN CONTAINED IN THE DIFFERENT GROUPS IN WEATHERED BROWN PEAT.

				Nitrogen extracted.			Ammoniacal nitrogen originally contained in peat.		
No. of expt.	Oven-dried peat.	Total nitrogen in peat.	Strength of acid. Per cent. by weight.	Gram.	Per cent. of total nitrogen in peat.	Per cent of oven-dried peat.	Gram.	Per cent. of total nitrogen in peat.	Per cent. of oven-dried peat.

TABLE V (*Continued*).

No. of expt.	Amido nitrogen.			Diamino nitrogen.			Monamino nitrogen.		
	Gram.	Per cent. of total nitrogen in peat.	Per cent. of oven-dried peat.	Gram.	Per cent. of total nitrogen in peat.	Per cent. of oven-dried peat.	Gram.	Per cent. of total nitrogen in peat.	Per cent. of oven-dried peat.
1	0.03773	14.62	0.393	0.0	0.0	0.0	0.11914	46.15	1.24
2	0.04058	15.72	0.423	0.0	0.0	0.0	0.13288	51.48	1.38
Av.,	....	15.17	0.408	...	0.0	0.0	....	48.81	1.31

By calculating the data in Table V to the nitrogen in solution as a basis, we get the following table:

TABLE VI.

Number of experiment.	Nitrogen in solution as				Total nitrogen in solution.
	Ammoniacal nitrogen originally contained in peat.	Amido nitrogen.	Diamino nitrogen.	Monamino nitrogen.	
1	0.30	23.99	0.0	75.71	100
2	0.28	23.33	0.0	76.39	100
Average,	0.29	23.66	0 0	76.05	100

When we compare Tables V and VI with Tables III and IV, we can readily see that certain changes took place in the nitrogenous groups by virtue of the agencies active in the weathering process. In the first place we notice that whereas in the brown peat, prior to the weathering process, the percentage of ammoniacal and amido nitrogen was 0.041 and 0.439, it changed to 0.005 and 0.408, respectively, in the weathered peat. Thus, through the weathering, a total decrease of 0.067 per cent. of ammoniacal and amido nitrogen took place, through leaching or some other cause. This may account for the fact that while the brown peat had 2.52 per cent. of ammoniacal and 26.80 per cent. of amido nitrogen, the weathered brown peat had 0.29 per cent. and 23.66 per cent., respectively, calculated to the nitrogen in solution as basis. This, as well as the disappearance of the diamino nitrogen in the weathered peat, must have necessarily increased the percentage of monamino acids in the weathered peat. It should, however, be borne in mind that, while the estimations of ammoniacal and amido nitrogen give accurate results, the determination of diamino nitrogen is not quite satisfactory. This influences, of course, the monamino nitrogen, since the latter is calculated by difference.

Considering the changes in the weathered peat, the assumption was justified that the solubility of the nitrogenous substances in the peat must have changed. From Table I it was evident that the solubility in water of the nitrogenous bodies contained in the brown peat is very small. It was of interest to learn the solubility in water of the weathered brown peat. For this purpose a few grams of peat were transferred to a flask, a definite amount of water added, mixed, digested, then filled up usually to 500 cc., mixed, filtered, through a dry filter, and two portions of 200 cc. each taken for Kjeldahlization. The nitrogen thus found was recalculated to the total volume. Table VII shows the results of these experiments:

TABLE VII.—THE SOLUBILITY IN WATER OF THE NITROGENOUS BODIES IN WEATHERED BROWN PEAT.

Number of experiment.	Oven-dried peat. Grams	Distilled water. Grams.	Hours digested.	Method of digestion.	Nitrogen extracted. Gram.	Per cent. of total nitrogen in peat.	Per cent of oven-dried peat.
1	4.798	400.0	10	Autoclave at $^3/_4$ to $^7/_8$ atm. pressure,	0.01172	9.08	0.25
2	2.8788	300.0	16	Boiling under reflux condenser,	0.00685	8.85	0.24
3	4.798	500.0	60	Shaken 10 minutes each hour, room temperature,	0.00300	2.32	0.06

From these experiments it follows that the solubility in water of the nitrogenous compounds in the weathered brown peat increases with the rise of temperature. This was also the case with the brown peat as dug from the bog, as can be seen from experiments 10 and 11, in Table I, and holds true also for the black peat. In other words, the solubility in water of the nitrogenous compounds in the various types of Michigan peat is in certain limits a function of the temperature. This being the case, we can further assume that the peats digested at higher temperature and pressure in a suitable autoclave will give a larger amount of water-soluble compounds than was obtained, for instance, in experiment 1, Table VII. That digestion at a higher temperature gives a higher percentage of water-soluble nitrogenous compounds is very likely due, in part, to hydrolysis of the nitrogenous bodies present in the peat.

By comparing Tables IV and VI it is readily seen that only about ten per cent. of the nitrogen in acid solution (and still less of the total nitrogen in the peat) has changed during weathering during two or three years, and that, in addition, the changes of the nitrogenous bodies did not go far enough to be converted, for instance, into ammoniacal nitrogen.

Conclusions.

While the data in hand do not warrant conclusive deductions as to the agricultural value of peat soils, for which further investigation will be necessary, the results obtained and given in this paper permit of drawing the following conclusions:

1. There are no nitrates in the types of Michigan peat soil examined.

2. The amount of ammonia is small, ranging from a few thousandths to a few hundredths of one per cent., this representing the nitrogen available immediately as plant food. In the case of the brown peat, the amount of ammonia is sufficient to meet the needs of one or two crops, as is evident from the following: There are in an acre-foot in round numbers 170 tons of oven-dried peat, with 0.041 per cent. ammoniacal nitrogen, making 0.0697 ton or 139.4 pounds nitrogen as ammonia.

3. Practically all the nitrogen in the peat is of organic nature.

4. The bulk of the organic nitrogen, namely from two-thirds to three-quarters calculated upon the nitrogen in solution, by boiling with acids, is present in the form of monamino acids, about one-quarter in the form of amides and the rest of the nitrogen represents diamino acids.

5. Through weathering, the organic nitrogenous bodies present in the brown peat change quite slowly.

REVIEW.

SOME RECENT ADVANCES IN ORGANIC CHEMISTRY.

Jan. 1, 1908–July 1, 1909.

BY L. H. CONE.

Received December 13, 1909.

Among the advances in organic chemistry during the last few years which have been remarkable for the difficulty of the experimental work involved are those which have been made at the border line between pure organic and physiological or biochemistry. These have deservedly attracted very wide attention.

Proteins.—Naturally one thinks first of Fischer's already classic work on the proteins when biochemistry is brought under discussion. This work has been steadily continued and polypeptides have been prepared of every naturally occurring amino acid, with the exception of five, which are very difficult to obtain or for which special methods will have to be worked out. The number of polypeptides isolated from the partial hydrolysis of proteins has constantly increased and five of these so isolated have been found to be entirely identical with those previously prepared synthetically in the laboratory.[1] Thus Fischer's theory of the protein constitution has been steadily strengthened. A discussion of the impetus which this theory has given to the more scientific study of problems of digestion, of assimilation, and of ferment action, lies without the province of this review, but a casual glance at the physiological literature will show the valuable service which the theory is rendering.

Early in the study of the polypeptides it became apparent that in order to obtain any large number of derivatives of the hydroxyamino acids some method would have to be devised for the temporary protection of the hydroxyl group so that hydroxyamino acid chlorides could be prepared. Fischer[1] has solved the problem by shaking the hydroxy acid to be protected, in alkaline solution with chlorocarbonic methyl ester, when the carbomethoxy group is introduced.

---

[1] "Abderhalden-Physiologische Chemie," 2nd Edition, p. 258 (1908).

$$HOC_6H_4CH_2.CH.NHR.COOH + CH_3OCOCl = CH_3OCO.OC_6H_4CH_2.CH.NHRCOOH + HCl.$$

The derivative thus obtained can be readily changed into the acid chloride by the action of phosphorus pentachloride and the acid chloride can be used for condensations. In the condensed product the hydroxyl group can easily be regenerated by hydrolysis with alkali. By means of this reaction a tetrapeptide, hitherto unattainable, containing tyrosine, has been prepared. The method has, however, a wider application in the synthesis of aromatic hydroxyketones, of which Fischer has prepared a number hitherto obtainable only with difficulty. He has carried the reaction still further and has prepared a number of gallic acid derivatives, among them a crystalline compound which was probably digallic acid.[2] This has not as yet been obtained entirely pure, so its relation to tannic acid is still uncertain.

Fischer's studies of the optical properties of the amino acids have also led to valuable results. Together with Raske[3] he treated the ethyl ester of *l*-serine with phosphorus pentachloride and obtained α-amino-β-chloropropionic ethyl ester. On reduction this yielded *d*-alanine. By treating the same chlorine derivative with barium hydrosulphide they obtained *l*-cysteine, which on oxidation gave *l*-cystine. This series of reactions proves that *l*-serine, *d*-alanine and *l*-cystine, the naturally occurring forms of these acids, all have the same configuration. Previously Fischer and Jacobs[4] had shown that *l*-serine gives *l*-glyceric acid with nitrous acid, Neuberg and Silberman[5] had shown that *l*-glyceric acid and *l*-tartaric acid have the same configuration, and Fischer had connected the configuration of *d*-tartaric acid with rhamnose, so that if all steps in the work were correct we have the beginning of a rational classification of the optically active mono-amino acids. Some doubts have been thrown on the correctness of the results of Neuberg and Silbermann however, so that the relationship between the amino acids and glucose is not yet entirely certain.

The results obtained by Fischer and Scheibler[6] in their study of "Walden's reversal" are interesting but too complex to be given here.

Nucleic Acids.—The problem of the constitution of the nucleic acids has been a difficult but attractive field. It has been known for some time that the nucleic acids have three constituents, carbohydrate, phosphoric acid, and purine or pyrimidine bases. The manner and order of linking of these constituents have not been known nor has the carbohydrate constituent been identified beyond question. That the carbohydrate in most nucleic acids is a pentose is now generally agreed, and Levene and Jacobs[7] have very recently shown that in four nucleic acids examined by them the same pentose is present and this pentose is very probably *l*-ribose. Burian, through his studies upon the diazonium compounds of the purine bases, has rendered it very probable that the purine group is bound in the nucleic acid molecule through its imide hydrogen in the position seven.[1] No sharp experimental evidence has, however, been brought to show the order of coupling of the constituents in the molecule till recent papers by Levene and Jacobs.[2] By acid hydrolysis they obtained a phosphoric acid-pentose complex which had strong reducing power and in which therefore the aldehyde group of the pentose was free. By neutral hydrolysis of the barium salts of several nucleic acids they then obtained a purine base-pentose complex which had no reducing power. From these facts they conclude that the pentose must be coupled ester-like through one of its hydroxyls to the phosphoric acid and glucoside-like through the aldehyde group to the purine base. Guanylic acid would be then as follows:

---

[1] *Ber.*, 41, 2860 (1908).

[2] *Ibid.*, 41, 2875 (1908).

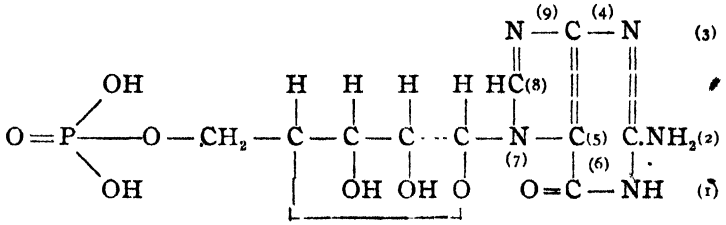
[3] *Ibid.*, 40, 3717 (1907); 41, 893 (1908).

[4] *Ibid.*, 40, 1057 (1907).

[5] *Z. physiol Chem.*, 44, 134 (1905).

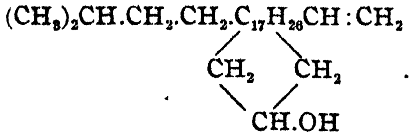
[6] *Ber.*, 41, 889, 2891 (1908).

[7] *Ibid.*, 41, 2703 (1908); 42, 335, 1198, 2102, 2469 and 2474 (1909).



Such a complex they call a "mono-nucleotide" and suggest that the nucleic acids are made up of several of these complexes all alike or different as the case may be, linked together through the phosphoric acid, just as the proteins are composed of polypeptides bound together and the polysaccharides of mono-saccharides coupled in chains of varying length.

Cholesterol.—Through the painstaking work of Windaus[3] a great deal has been added to our knowledge of the constitution of cholesterol. By the judicious application of different oxidizing agents in rotation he has been able to break off various side chains till finally an acid, very resistant to oxidation, has been obtained with the compact formula $C_{17}H_{26}(COOH)_4$. The various steps in the oxidation process are too numerous to be given here, but from the results Windaus concludes that he is justified in writing cholesterol, which has the empirical formula $C_{27}H_{46}O$, as



From the structure given it is apparent that of the twenty-seven atoms of carbon in the molecule the functions of ten have been determined.

Chlorophyll.—Although the work of Willstätter[4] and his co-laborers on chlorophyll began to appear several years ago, it has continued into the time supposed to be covered by this review. The conclusions which they have reached may be summarized very briefly. Chlorophyll occurs in at least two different forms, amorphous and crystalline. The amorphous chlorophylls, which apparently predominate in most plants, are all esters of the same high molecular weight unsaturated alcohol, phytol, $C_{20}H_{40}O$, with different complex acids. The crystalline varieties, if they are esters at all, contain only low molecular weight alcohols so soluble in water that they have escaped detection. Both varieties of chlorophyll contain magnesium in the acid part of their molecules, so combined as to be very resistant to alkalies. This magnesium is readily split off by dilute acids and the organic residues remaining may be broken up by severe treatment with strong acids and alkalies into less complex products, a number of which have been isolated and analyzed. Willstätter's results have generally been accepted. Stoklasa[1] has, however, recently published a series of analyses of samples of chlorophyll prepared by himself, in all of which he found very appreciable quantities of phosphorus. The phosphorus is bound in such a labile manner, according to him, that Willstätter removed it by his process of purification. The majority of chemists will probably accept Willstätter's conclusions, however, that the phosphorus is an adhering impurity properly removed during purification.

Carbohydrates.—A number of articles of interest have appeared dealing with the carbohydrates and their derivatives. Fischer and Raske[2] have applied the methods of König and Knorr[3] for the preparation of glucosides from acetobromoglucose and alcohols. The essential point of this method is that the alcohol and the acetobromoglucose are shaken together in a neutral organic solvent in the presence of silver carbonate. The silver binds the hydrobromic acid so that the reaction goes to end in neutral solution. The tetraacetylglucosides were obtained in crystalline form and the acetyl groups removed by hydrolysis with barium hydroxide. By this method glucosides of aliphatic, aromatic, and hydroaromatic alcohols were prepared. The glucosides of menthol and borneol thus obtained are the first terpene glucosides to be described. All of the glucosides prepared were hydrolyzed by emulsin and are therefore probably β-glucosides.

Hudson[4] has pointed out certain relations between the molecular rotations of the various sugars. Evidence indicates that α- and β-glucose are both lactones and differ from each other only sterically. This steric difference must be entirely in the fifth, new asymmetric carbon atom which is produced when the aldehyde group of glucose is hydrated and then dehydrated to form a lactone. If the theory of optical superposition holds[5] the optical effect of the four asymmetric carbon atoms common to both forms must be the same. Let this effect be B. The rotation produced by the fifth asymmetric carbon atom will be the same numerically in both forms but will be different in sign, and can therefore be represented by ±A. One form will thus have a rotation of A + B and the other of —A + B, the sum of which will be 2B and the difference 2A. Other aldoses differ from glucose in the configuration of the four originally asymmetric carbon atoms. In their α- and β- forms the fifth or end asymmetric carbon atoms are identical with those in the two forms of glucose, respectively, *i. e.*, ±A. Their rotations may then be represented by A + B′ and —A + B′, the sum of which is 2B′ and the difference 2A. This means that the α- and β-forms of all aldohexoses should have a common difference 2A. The same reasoning may be applied to other sugars. The theory was tested on a number of sugars whose α- and β-forms are known and found to agree fairly well with the facts. If the principle proves to have general application it will be of value in predicting the rotatory power of forms which have not as yet been isolated and will aid in the rational classification of forms as α- or β-derivatives.

Two years ago Slator[1] showed that lactic acid which is added to a sugar solution undergoing alcoholic fermentation is not affected and can be recovered at the end of the fermentation unchanged. He concluded therefore that lactic acid cannot be an intermediate product in the alcoholic fermentation of sugar. Buchner and Meisenheimer[2] did not accept his conclusions at the time but recently they have repeated his experiments, found them correct, and are inclined to accept his conclusions.[3]

Alkaloids and Terpenes.—The constantly growing volume and complexity of the work on alkaloids and terpenes makes it exceedingly difficult for one not specializing in these fields to choose from among the mass of material those results which stand for real advances.

Leuchs[4] has obtained crystalline acids as the result of the oxidation of strychnine and brucine in acetone solution with potassium permanganate. The acids from the two alkaloids are very similar and each contains four atoms of oxygen more and two atoms of hydrogen less than the alkaloid from which it was produced. From this the conclusion seems justified that a group $\underset{|}{\mathrm{HC}} = \underset{|}{\mathrm{CH}}$ was changed into two carboxyl groups and that a secondary alcohol group was oxidized to a ketone carbonyl. In a later paper Leuchs and Schneider[5] describe crystalline sulphonic acids of both alkaloids which they prepared by treating their solutions in sulphurous acid with manganese dioxide. The reaction apparently proceeds according to the following general equation:

$$O + HO_3SH + H.R = RSO_3H + H_2O,$$

and should therefore yield sulphonic acids of any substance RH, in which H is fairly easily oxidized away. The study of these new derivatives of strychnine and brucine bids fair to aid very materially in throwing light upon their constitutions.[6]

Wollfenstein[7] has described and patented a new method for the preparation of atropine and similar alkaloids from tropine and tropic acid or from tropine and other hydroxy acids as the case may be. Atropine is an ester of tropine and tropic acid, and therefore if tropic acid chloride could be prepared and would react normally with tropine the preparation of atropine would probably be very much more quantitative than by the methods at present in vogue.[1] Tropic acid is α-phenyl-β-hydroxypropionic acid and here, as in the case of Fischer's work with tyrosine, the hydroxyl group led to complications. Wollfenstein therefore prepared acetyl tropic acid, from this the acid chloride, and then condensed the acid chloride with tropine. The acetyl atropine thus obtained hydrolyzes into acetic acid and atropine merely by dissolving in water.

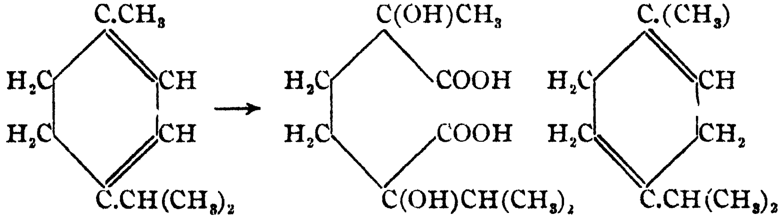
$$\begin{array}{l} CH_2.CH—CH_2 \\ \quad NCH_3 \; CH.O.COCHCH_2OCOCH_3 + H_2O = \text{atropine} + \text{acetic acid.} \\ CH_2.CH—CH_2 \qquad C_6H_5 \end{array}$$

Acetyl atropine.

Wallach[2] has shown that ordinary terpinene is not a homogeneous substance but that it is a mixture of which the main constituent is certainly α-terpinene or $\Delta^{1,3}$-dihydrocymol (I). Samples of terpinene prepared by four different methods, on oxidation all gave an erythrol, $C_{10}H_{16}(OH)_4$, which, on further oxidation yielded α,α′-dihydroxy-α-methyl-α′-isopropyladipic acid (II),



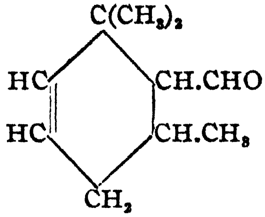
I. II. III.

This acid could come only from α-terpinene (I). Besides the above oxidation products another erythrol was obtained which could not be further oxidized to a substituted adipic acid. This proves that another hydrocarbon is present with α-terpinene in ordinary terpinene, and Wallach concludes that this other hydrocarbon must be γ-terpinene (III). The reasons for this conclusion are too complex to be given here.

A long paper in Liebig's *Annalen* by Merling and Welde[3] on the synthesis of violet perfumes is a valuable contribution to that complex field. Their object was to determine as far as possible the constitutional conditions essential for this especial odor. They first proved that only those aldehydes of cyclo-citral which contain methyl groups in the positions adjacent to the aldehyde group give a compound with the odor of violets on condensation with acetone. This configuration is present in β-irone, the natural oil of violets, which is the condensation product of Δ_4-cyclocitral aldehyde (I) with acetone:

---

[1] *Arch. Pharm.*, 240, 498 (1902).
[2] *Ann.*, 362, 285 (1908).
[3] *Ibid.*, 366, 119 (1909).



I.

They then tested non-cyclic derivatives with the aldehyde group between methyl groups as *e. g.*, isopropyl ethyl acetaldehyde,

$$C_2H_5.CH(CHO).CH(CH_3)_2,$$

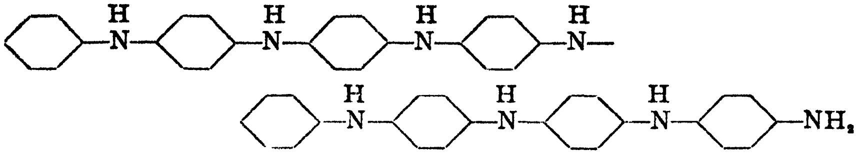
and found that the acetone condensation product of this, while it had a pleasant odor, had no suggestion of violets. The presence of the aldehyde group in a hydroaromatic ring, between methyl groups, seems then to be essential for the production of a violet perfume. The remainder of their paper is taken up with a description of the methods of preparation of the materials for the synthesis of α- and β-irone which are Δ_3- and Δ_4-cyclocitral aldehyde condensation products with acetone, respectively. They conclude that α-irone has no perfume value above that of the natural oil of violets, which is β-irone, and neither have any advantage over the ordinary commercial product which is a mixture of α- and β-ionone, the Δ_2- and Δ_1 derivatives of the same cyclocitral aldehyde condensation product with acetone as the two irones. In passing, it may be worth mentioning that the German patents on ionone expired in April of 1908.

Chemistry of Dyestuffs.—Important advances have been made in the field of the natural dyestuffs so that the constitution of brazilin, haematoxylin, and their derivatives, may be considered as in the main established. Credit is chiefly due to W. H. Perkin, Jr.,[1] and his co-workers for these results, but the work is too complex to permit its being given even in outline in this paper.

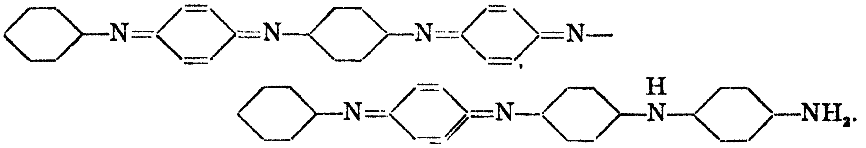
Aniline black in its extreme insolubility and great stability has long defied attempts to gain an insight into its constitution. Willstätter,[2] in his characteristically concise manner, has attacked this problem with co-workers and has apparently been able to solve it. He has shown that the oxidation of aniline to quinone does not take place by way of phenylhydroxylamine as an intermediate product, but that aniline black is certainly produced as one of the steps. The amount of oxygen necessary to form aniline black was found to be 1.25 atoms for every molecule of aniline and the black thus produced had the composition $C_6H_{4.5}N$. The questions remaining to be settled were, how many of these units, $C_6H_{4.5}N$, are there in the molecule of aniline black, and how are they combined with each other? The first question was answered by hydrolyzing samples of the black with sulphuric acid when exactly one-eighth of the total nitrogen was split off as ammonia. Quantitative measurements of the amount of quinone obtained by the oxidation of the aniline black answered the second question. A yield of 93–95 per cent. of quinone was obtained. The only compound which seems to satisfy these facts is that one whose leuco base is the following:

[1] *J. Chem. Soc.*, 93, 489, 1115 (1908).

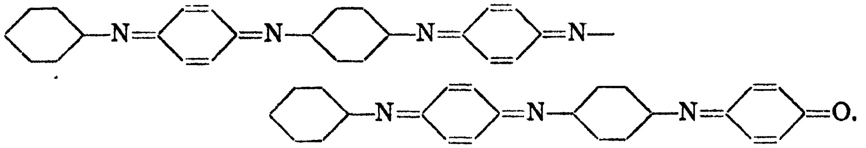
[2] **Willstätter und Dorogi, *Ber.*, 42, 2147, 4118 (1909).**



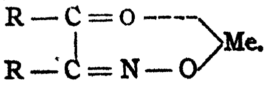
A chain of this type, with continuous para linkings, is the only one which could give a quantitative yield of quinone. The terminal amino group in such a chain is the only one which would be affected by hydrolysis, and therefore if the compound gives up one-eighth of its nitrogen on hydrolysis the molecule must contain eight amino groups, and therefore eight aniline residues in all. The black under discussion would then be $(C_6H_{4\cdot5}N)_8$ or $({}_{48}H_{36}N_8)$, which demands that six hydrogens be oxidized away from the above leuco base to form the dye.



This aniline black is in color blue-black and forms green salts, so it is not the valuable aniline black of commerce. To distinguish it from other blacks Willstätter calls it a triquinoid black. By further regulated oxidation a tetraquinoid black is produced in which the terminal benzene ring substituted with the amino group has become quinoid. This black, whose salts are also green, gives quinone quantitatively on oxidation and also yields one-eighth of its nitrogen on hydrolysis. By this hydrolysis a pure black is produced which does not change color with acids and which seems to be identical with the commercial black. This product must be represented by the following formula:



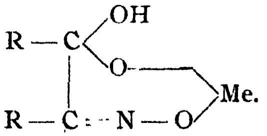
Werner[1] has made use of his theory of inner complex salts in an attempt to explain the nature of the metallic compounds (lakes) formed by mordanting dyes. He assumes the metal in these compounds to be a member of a heterocyclic ring, held there by one principal and by one secondary valence. The differences in color between the true salts of the metals and their lakes are ascribed to the peculiar influence of the secondary valence. The great stability of the lakes and the failure of the metals in them to respond to the ordinary ionic tests are explained on the same basis. The metallic compounds of many simple substances were discussed as illustrations of the theory, as *e. g.*, those of mono-oximes of diketones which he supposes to have the constitution



---

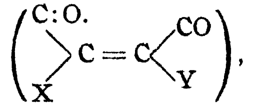
[1] *Ber.*, 41, 1062 (1908).

Liebermann[1] replies to Werner by claiming that the peculiarities of the lakes may all be explained by his old theory of the formation of a heterocyclic ring in which the metal is held by two full valences. Compounds of the type of the above mono-oximes may be explained by assuming that they react in their hydrated form and produce a metallic compound with the structure

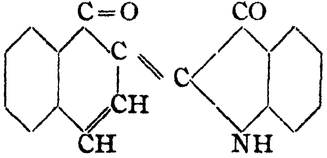


Liebermann's view-point has the advantage of employing only the accepted theory of valence.

Great interest has centered in the last few years in the preparation of dyes suitable for use in the hydrosulphite vat The majority of these dyes are either of the indigo type or derivatives of anthraquinone. The valuable properties of thioindigo have greatly stimulated the preparation of new dyes of the indigo type. Friedlander[2] has coined the word "indigoid" as a class name for all compounds containing the chromophoric complex



in which the ring systems may be either aromatic or aliphatic and in which X and Y may be C, N, S or O. A great variety of compounds of this type can be prepared, of which the compound obtained by the action of isatine chloride on α-naphthol may be cited as an example:



Naphthalin-indole-indigo.

The technically important dyes of this class have been mostly derivatives of thioindigo because the introduction of substituents in the indigo molecule does not very materially alter the color.[3] Some halogenated indigos have been put successfully on the market and Friedländer[4] has shown that the "antique purple" of the classic period was a dibromo indigo obtained from a variety of snail *Murex brandaris* still common in the Mediterranean. Of thioindigo and its halogenated derivatives there are some fifteen different commercial marks for sale, which yield shades from red over orange to the blue and bright blue-violet. A number of these are unsymmetrical derivatives from hydroxythionaphthene and isatin or their derivatives as *e. g.*, thioindigo-scarlet R, which has the following structure:

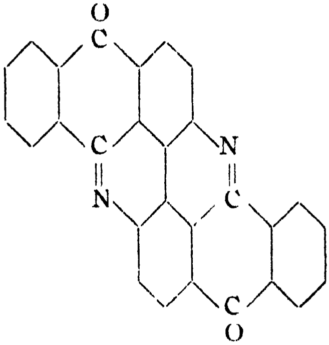
The commercial success of indanthrene and flavanthrene has served to stimulate the production of anthraquinone dyes till at present a very wide range of colors can be obtained with these products. The chemistry of flavanthrene has been studied by Roland Scholl[1] who, in 1907, prepared the compound synthetically, showing it to have the following constitution:



In continuing his work Scholl has obtained seven reduction products of flavanthrene, finally preparing the oxygen-free base flavanthrine.[2]

Constitution and Color.—The vibratory nature of light makes it seem reasonable to conclude that colored substances, which are so by virtue of their power to absorb certain frequencies of vibrations, must have some sort of vibratory motions within themselves which give to them their selective absorptive power. In its ultimate analysis then the cause of color is vibration within the molecule. Whether or not we know enough of molecular physics to attempt at the present time the statement of theories as to the nature of these vibrations is an open question. A number of English investigators[3] have stated such theories, basing them on the results of their spectroscopic studies. Whether or not these theories will be of value to the science, time only will tell.[4] Their experimental work has, however, been of inestimable value in drawing attention to the necessity of applying spectroscopic methods to the study of the problem of color. Many of their observations have shown interesting analogies or have contributed to the settling of structural questions. Two examples from recent papers by Baly may be cited: 1,4,5,8-tetrahydronaphthalene has the same type of absorption spectrum as *p*-xylene, which serves to emphasize the similarity of their structures.[5]

---

[1] *Ber.*, 40, 1691 (1907).

[2] *Ibid.*, 41, 2304, 2534 (1908).

[3] A review of these theories by W. J. Hale is to be found in *Pop. Science Monthly*, 72, 116 (1908).

[4] Cf. Michael, *Ann.*, 363, 45 (1908).

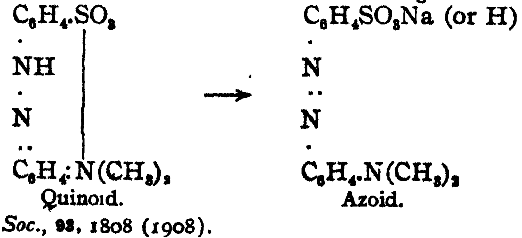
[5] *J. Chem. Soc.*, 93, 1902 (1908).

Cinnamylidenemalonic acid and its esters are yellow but its salts are colorless. The absorption spectra of all three, acid, ester, and salt are alike, thus showing that they are probably all similarly constituted.[1]

Hantzsch[2] has continued to bring forth much evidence in support of his theory that two substances differing in color, though they may be identical in all other properties, must be different in constitution. Hantzsch's theory is in fact a claim for the sufficiency of our present structural hypothesis in explaining color, as far as it can be explained in at all tangible terms. To him every change in color must be accompanied by a change in constitution, and such a change in constitution as can be expressed in terms of the generally accepted methods of structure writing.[3] The extensive debate between Hantzsch and Kaufmann during the past year or so has hinged upon this point. Kaufmann[4] claims that some substances with fixed constitutions will vary their real and their fluorescence color under the influence of mild external agents such as solvents, etc. There must be some variable in the molecule whose changes are casually connected with these variations in color. This variable, non-constitutional part he assumes to be "residual affinities" of the chromophore and the auxochrome groups. The state of these residual affinities, whether in combination with neighboring carbon atoms, with each other, or with molecules of the solvent determines the color of the substance. In terms of this theory all changes of color or of fluorescence can be readily explained, naturally enough, because residual affinities are of such elastic, undefined form that they can readily be molded to suit every demand made upon them. They and their near relatives, partial valences and secondary valences, are in fact the ghosts of modern chemistry. They walk among us constantly so that we all feel their presence, but no one has as yet been able to define their shapes or their sizes or to lay a hand upon them.

Hantzsch's theory, although it fails to explain much, certainly has the advantage of being tangible and of offering many opportunities for the application of experimental tests. A few examples from his work will suffice for illustration. Helianthin in its solid form is violet, in its solutions it is orange, and its sodium salt both in the solid form and solution is orange.[5] The absorption spectra of its orange solutions both as free acid and as salt are identical with similar derivatives whose azo character is not questioned. He concludes, therefore, that the orange forms are all azoid and that the violet form is quinoid as given in the following structures:

Violet. Orange.



$$\begin{array}{l} C_6H_4.SO_3 \\ \cdot \\ NH \\ \cdot \\ N \\ \cdot\cdot \\ C_6H_4{:}N(CH_3)_2 \end{array} \longrightarrow \begin{array}{l} C_6H_4SO_3Na\ (\text{or H}) \\ \cdot \\ N \\ \cdot\cdot \\ N \\ \cdot \\ C_6H_4.N(CH_3)_2 \end{array}$$

Quinoid. Azoid.

---

[1] *J. Chem. Soc.*, 93, 1808 (1908).

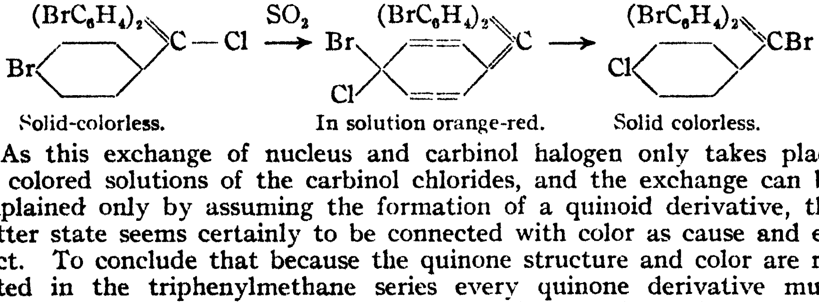
[2] *Ber.*, 41, 1171, 1189, 1204, 1216, (1908); 42, 889, 966, 986, 1000, 1007 (1909).

[3] In his last papers Hantzsch describes certain color changes which he claims are not accompanied by actual structural variations. Attempting to explain these facts he also falls back on secondary valences, whose variations he supposes to cause these more subtle color changes. *Ber.* 42, 985 (1909).

[4] *Ibid.*, 41, 4396, 4413 (1908).

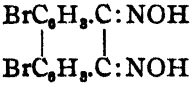
In another paper he describes a large number of salts of oximino ketones, R—CO—CNOH—R, with colorless cations.[1] These salts exist in the greatest variety of colors and mixed shades and he concludes that every salt with a distinctive color must be constitutionally different from salts of other colors and from the colorless form. In the work there is, however, a notable lack of distinctive proof, by reaction or by synthesis, which would positively connect a constitution with a color. The above assumption, for example, that the violet form of helianthin is a quinoid derivative is at best only very probable and it is devoid of actual experimental proof, other than the optical examination of similar derivatives with similar colors.

Gomberg[2] has been able to furnish definite experimental evidence that certain changes from colorless to colored forms in the triphenylmethane series are accompanied by a simultaneous transformation from benzoid to quinoid configurations. *p*-Tribromotriphenylcarbinol chloride, a colorless solid, dissolves in the ordinary organic solvents to a colorless solution but its solution in liquid sulphur dioxide is orange-red. When any of its colorless solutions in organic solvents are evaporated to dryness the original colorless carbinol chloride is recovered unchanged. If, however, the colored solution in liquid sulphur dioxide is evaporated to dryness the result is entirely different. A colorless solid is obtained which is mostly *p*-*p*′-dibromo-*p*″-chlorotriphenylcarbinol bromide. This means that the carbinol chlorine has exchanged places with one of the nucleus bromine atoms. The mechanism of the transformation will be clear if the following equation is examined:



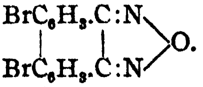
Solid-colorless. In solution orange-red. Solid colorless.

As this exchange of nucleus and carbinol halogen only takes place in colored solutions of the carbinol chlorides, and the exchange can be explained only by assuming the formation of a quinoid derivative, the latter state seems certainly to be connected with color as cause and effect. To conclude that because the quinone structure and color are related in the triphenylmethane series every quinone derivative must always be colored would, however, be stretching the theory further than the facts at present known warrant. A case recently observed by Schmidt and Mezger[3] illustrates this point. 2,7-dibromophenanthraquinone and its dioxime are both colored, but the oxime anhydride which still has the quinone configuration unchanged is colorless:



$$\begin{array}{l} BrC_6H_3.C:NOH \\ \quad | \qquad\ | \\ BrC_6H_3.C:NOH \end{array}$$

Ocher-yellow.



$$\begin{array}{l} BrC_6H_3.C:N\diagdown \\ \quad | \qquad\ | \qquad\quad O. \\ BrC_6H_3.C:N\diagup \end{array}$$

Colorless.

Tautomerism.—Michael[4] has discussed the phenomena of tautomerism and has concluded that two distinct types of reactions are ordinarily classed under this one head. These two classes he distinguishes as (1) desmotropism which is the reversible change of one form into another by the shifting of a hydrogen atom within the molecule and (2) merotropism, which is the irreversible change of one substance into the derivative of another under the influence of an active chemical agent. Both reactions are resultants of two factors, the free energy in the molecule, which naturally tends toward a minimum, and the chemical affinities of the specific groups undergoing change. These ideas Michael has illustrated on numerous examples. With various co-laborers[1] he then investigated several reagents to determine their value as diagnostic agents for stable keto or enol forms. Acetic anhydride, acetyl chloride and phenylisocyanate he found to give unreliable results, but tertiary amines, especially triethyl- and tripropylamine he found gave very consistent results. Tertiary amines unite with enols to form ammonium salts but do not form additive compounds with keto derivatives. The tertiary amines have little power to change keto derivatives over into enols so that only with desmotropes are the results of such a character that they require care in interpretation. A stable keto merotrope will not react with tertiary amines, but a stable enol merotrope will form ammonium salts with considerable evolution of heat, which ammonium salts will yield the free enol again on treatment with acid. A keto desmotrope may be changed over into the enol form, or *vice versa*, under the influence of tertiary amines, according to the stability relations of the two forms. From results with this tertiary amine reaction Michael and Smith classify a number of compounds as stable keto derivatives which have ordinarily been considered to be mixtures of the two forms in equilibrium with each other, *e. g.*, diacetylmethane and acetoacetic ester. This conclusion is not in harmony with the results of numerous physico-chemical investigations, but Michael and Smith point out that these physico-chemical results do not harmonize among themselves and are therefore never to be accepted when they contradict chemical evidence. It is interesting to note in this connection that Auwers[2] has called attention to the fact that physico-chemical methods have been of much less value in clearing up the constitution of the hydroxyazo compounds than have the purely chemical methods.

[4] *Ann.*, 363, 20 (1908).

Mannich and Hancu[3] have shown that cyclic ketones, and Hancu[4] has shown that symmetrical aliphatic ketones are tautomeric substances (merotropes according to Michael), in that they yield more or less of the acetyl derivatives of their enol forms on long heating to high temperatures with acetic anhydride. On saponification the acetyl derivatives yield only the original ketones.

Gabriel[5] has shown that where two substituted imidazoles of the form

would be expected only one can be obtained by synthesis. He therefore concludes that this is a case of "virtual tautomerism," where the imide hydrogen atom is in equilibrium between the two nitrogens.

Catalysis.—The mechanism of the catalysis of various organic reactions by acids and bases has been the subject of a number of investigations. Stieglitz[1] and Acree[2] have both obtained experimental evidence in favor of the theory that the catalyzer forms salts with some substance in the reaction undergoing catalysis. Stieglitz investigated the hydrolysis of imino esters and concluded that the rate of hydrolysis of the esters in acid solution is proportional to the concentration of the cation formed by the ester with the acid, and in alkaline solution is proportional to the concentration of the anion formed by the ester with the base. Acree studied the formation of acetooxime from acetone and hydroxylamine and concluded that the catalysis of this reaction by acids and bases depends in both cases upon salt formation with the hydroxylamine. Both investigators agree that the definition of catalysis, as accepted a few years ago, covers only certain ideal cases. Further study is needed before a satisfactory new definition can be formulated. The majority of chemists will probably agree with Stieglitz, Acree and others, that catalyzers exert their influence through the formation of intermediate unstable compounds which probably are salts. Since the work of Collie, Werner, Baeyer, and a host of others on the oxonium theory, the idea that these intermediate compounds are in most cases oxonium salts has steadily gained ground. That they may be carbonium salts has been suggested by Stieglitz,[3] but he concludes that at present the preference must be given to the oxonium form. The author of this review believes, however, that in the end evidence will be found to indicate that these compounds, if salts at all, are really carbonium salts. He bases this view on two things: first, the position of carbon in the periodic system, which would indicate a base-forming power greater than that of either nitrogen or oxygen, and second, on the generally unsatisfactory nature of the evidence in favor of the oxonium theory.

Rosanoff and Prager,[4] and Michael,[5] have simultaneously called attention to the fact that hydrochloric acid, which has always been assumed to be, with a few exceptions, a favorable catalyzer for esterifications, is in a good many cases a negative catalyzer. Michael uses this fact as an argument in support of the theory discussed above, that the catalytic influence of hydrochloric acid upon esterification is due to an intermediate salt formed with the alcohol. Hydrochloric acid will then increase or diminish the rate of esterification according as the acid being esterified reacts more readily with this hydrochloric acid-alcohol complex or with the free alcohol. The chemical nature[6] of the acid undergoing esterification will thus determine whether hydrochloric acid will

[1] *Am. Chem. J.*, 39, 29, 166 (1908).

[6] Cf. Stewart, "Stereochemistry," p. 321.

act as a positive or a negative catalyzer. To determine the real rates of esterification of acids the reaction must be studied in the absence of all catalyzers. V. Meyer based his rule in regard to the esterification of di-*o*-substituted aromatic acids upon results obtained in the presence of hydrochloric acid. Hydrochloric acid acts toward the esterification of these acids as a negative catalyzer, but by heating them with alcohols alone they can be readily esterified. V. Meyer[1] was always very careful to state that his law held only for esterification in the presence of hydrochloric acid, therefore these new facts serve more to broaden his law than to contradict it. Rosanoff and Prager suggest the following wording so as to make the law general: "Aromatic acids, in which one or both of the positions ortho to the carboxyl group are occupied by substituents, unite with alcohols slower but not less completely than acids otherwise constituted."

Willstätter and Mayer[2] have revived a method, already patented and known in the chemical literature, for the reduction of unsaturated compounds with hydrogen at ordinary temperature in the presence of finely divided platinum. From phytol they thus prepared dihydrophytol, oleic acid ester gave stearic acid ester and benzoic acid gave some hexahydrobenzoic acid. Paal[3] has obtained the same results by the use of colloidal palladium.

The use of finely divided nickel oxide for the catalytic reduction of volatile organic substances at high temperatures has become general. Ipat'ev[4] has made several interesting observations on the finer details of this process. Nickel oxide, in an atmosphere of hydrogen, is reduced to metallic nickel at 200°, but when benzene is being reduced to hexahydrobenzene the nickel oxide is heated considerably higher without appreciable production of metallic nickel. If the nickel oxide is heated over the blast before using, its efficiency as a catalyzer is very considerably impaired. By analysis Ipat'ev showed that the unignited nickel oxide held a few per cent. of water and he attributes its better catalytic effect to this moisture. Senderens[5] has shown that silica and aluminium oxide have very peculiar effects upon the decomposition of alcohol and various organic acids at high temperatures. According to the previous history of the silica or the aluminium oxide employed as catalyzer, and the temperature at which the reaction is carried out, alcohol will produce a gas which is pure ethylene, or a mixture of ethylene and hydrogen, or practically all hydrogen. Acetic acid decomposes at 350° in the presence of aluminium oxide into acetone and carbon dioxide.[6] Ethyl ether breaks up at 300° into ethylene and water. If alcohol is passed over aluminium oxide below 300° at, *e. g.*, 240–260°, a good yield of ether is obtained with only slight quantities of ethylene.[7] Sabatier and Mailhe[8] have shown that a mixture of alcohol and ammonia passed over thorium

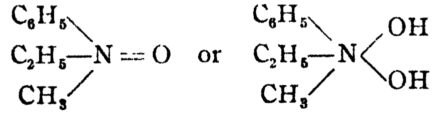
oxide at 360° will form primary ethylamine with some secondary amine and traces of the tertiary amine.

Stereochemistry.—The theory of Guye, that optical activity is a function of the differences between the weights of the groups about the asymmetric carbon atom, has been again brought into discussion. Recent writers[1] on stereochemistry agree that the theory is entirely insufficient, but because it is the only general theory of the relation between constitution and optical activity it still continues to suggest experimental work. Fischer and Flautau,[2] on the suggestion of van't Hoff, prepared propyl isopropyl cyanacetic acid and resolved it into its constituents. The theory of Guy requires that these constituents should be optically non-active, as the propyl and isopropyl group are identical in weight, but they were found to have an activity of ±11.4. Everat and Jones,[3] and Jones and Hill,[4] have examined a number of optically active ammonium derivatives and concluded that the constitutions of the groups about the asymmetric nitrogen have more influence than their weights. Bose and Willers[5] examined 42 optically active substances with seventeen different groups and conclude from their results that the theory of Guye is entirely at variance with the facts. Bose[6] suggests a modified form of Guye's equation for the asymmetry product in which no assumption is made as to the nature of the constants which represent the activity produced by each group about the asymmetric carbon atom. He then shows how such a modified expression suggests experimental tests which will either disprove or will furnish strong evidence in favor of the correctness of Guye's fundamental idea in regard to the asymmetry product. For the mathematical details of Bose's reasoning the original articles must be consulted.

Meisenheimer[7] has been able to prepare an optically active ammonium derivative where two of the five valences of the nitrogen are attached either to oxygen or to two hydroxyl groups:



Ethyl-methyl aniline oxide is optically active in aqueous solution as the free base, or in the form of its salts. As an explanation of this activity he assumes that four valences of the nitrogen atom are directed to the four corners of a tetrahedron and the fifth remains without fixed direction. The space arrangement then becomes similar to that about the asymmetric carbon atom. The two hydroxyls are not alike if the molecule is thus constructed, as one is fixed in position and the other is free to wander, so that the case under consideration would then really belong to the class of optically active ammonium derivatives having five unlike radicles. That the two hydroxyls of the hydrate form in its unionized state are really unlike seems very improbable to the writer of this review.

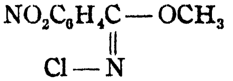
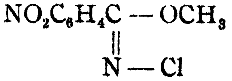
The phenomenon of auto-racemization so characteristic of the optically active ammonium salts has been investigated by E. Wedekind and his co-workers.[1] They have shown that when the active halogen salts are dissolved in chloroform the iodides racemize the most rapidly, the bromides next, and the chlorides are the most stable. This auto-racemization they proved to be due to the splitting of the ammonium salt into an alkyl halide and a tertiary amine, both of which are non-active.

Stieglitz and Hilpert[2] have isolated two forms of the chloroimido esters of several nitrobenzoic acids. These forms differ distinctly in physical properties, yet all of their reactions indicate that they are structurally identical. They must, therefore, be stereoisomers, probably geometrical isomers, of which one is the syn- and the other the anti-form:



$$\begin{array}{l} NO_2C_6H_4C - OCH_3 \\ \quad\;\;\;\;\;\;\;\;\; \| \\ \;\;\;\;\; Cl - N \end{array}$$



$$\begin{array}{l} NO_2C_6H_4C - OCH_3 \\ \quad\;\;\;\;\;\;\;\;\; \| \\ \quad\;\;\;\;\;\;\;\;\; N - Cl \end{array}$$

This is the first example of geometrical isomerism among derivatives where the nitrogen is attached on one side to a single element.

The limited space allotted for this review makes it impossible to even mention a great many of the valuable results obtained in organic chemistry during the past eighteen months. In view of the recent paper in THIS JOURNAL by W. A. Noyes[3] on "Molecular Rearrangements" that subject, which is at present receiving as much attention as any one field of organic chemistry, has not been discussed. Discussions of the special applications of general reactions, as Grignard's, and Friedel and Crafts' reactions, have been omitted, as well as descriptions of the synthesis of a vast number of new compounds belonging to already well-established classes.

NEW BOOKS.

Einführung in die allgemeine und anorganische Chemie auf elementare Grundlage. von DR. ALEXANDER SMITH, unter Mitwirkung des Verfassers übersetzt und bearbeitet von DR. ERNST STERN, Assistent am Königl. Material-prüfungsamt zu Gross Lichterfelde-West. Mit einem Vorwort von Dr. FRITZ HABER, ord. Professor an der Technischen Hochschule zu Karlsruhe. G Braun, Karlsruhe, i. B, 1909, pp. 677. Price, M. 9.

American chemists who owe so much of their advanced training to the German universities cannot fail to note with satisfaction that in reforming their methods of elementary chemical instruction the Germans are taking the American curriculum as a model. The German translation of Alexander Smith's laboratory manual which appeared some years ago has been widely adopted, and this excellent translation of the author's larger work may be expected to achieve an equal success. While the treatment of experimental material has remained unaltered, the theoretical portions of the book have been thoroughly revised by the translator with the coöperation of the author. The book is well introduced to German readers in a preface written by the broadest and surest of German teachers and investigators in chemistry.

[3] THIS JOURNAL, 31, 1368 (1909).

In this preface Professor Haber points out the three standpoints from which one may view the great domain of chemical science. The first is based on the comparison of the elements by means of the periodic system, the second on the qualitative representation of substances and reactions through structure formulas, and the third on a quantitative treatment of chemical phenomena according to the fundamental physico-chemical principles. A student who becomes equally familiar with these three methods possesses an immense advantage, comparable with that given by a mastery of several languages acquired in youth. While the use of a single view-point in the teaching of elementary chemistry may be attractive to both teacher and student, yet the more enthusiastically and emphatically the teacher develops this single system, the more difficult the student finds it, when occasion arises, to adopt another point of view. As a result we have physical chemists without the structure-chemical instinct, or organic chemists who lack physico-chemical insight. So misunderstandings arise, and each group seeing only the importance of its own problems forgets that after all there is but one Chemistry, in which the different methods are equally justifiable because equally fruitful. Professor Haber especially commends the book under review for its impartial and thorough treatment of all the general methods of chemistry.

GILBERT N. LEWIS.

General Chemistry for Colleges. By ALEXANDER SMITH, Professor of Chemistry and Director of General and Physical Chemistry in the University of Chicago. New York: The Century Co., 511 pp. Price, $2 15.

The method of treatment employed by the author in his "Introduction to General Inorganic Chemistry" has proved so satisfactory to large numbers of teachers throughout the country that this shorter course in which a similar method and arrangement are employed cannot fail to find a wide field of usefulness. The theoretical chapters differ materially from those of the larger work, and some of the descriptive matter contained in the latter has been omitted. There can be no doubt that the larger text-books of inorganic chemistry which are in common use contain much more information than can be readily assimilated by the average student in his first year of chemical study. It may be questioned whether this is not still true of the shorter course contained in this book.

THE ADIABATIC DETERMINATION OF THE HEATS OF SOLUTION OF METALS IN ACIDS.

[FIRST PAPER.]

By Theodore William Richards and Laurie Lorne Burgess

Received January 21, 1910

Contents.

Introduction, Discussion of Earlier Work, Materials Hydrochloric Acid Zinc, Aluminium, Magnesium, Cadmium, Iron, Apparatus: The Adiabatic Calorimeter, Thermometers, Stirrers, The Platinum Basket, Apparatus for Preventing Loss of Drops, Efficiency of Stirring, Correction for Heat Evolved in Stirring, Possible Errors Caused by Heat Exchange with Surroundings, Correction for Evaporation of Acid, The Heat of Solution of Metals in Concentrated Acids, The Heat of Solution of Zinc; Summary.

Introduction.

The heats of solutions of metals in acids are among the most essential and fundamental of thermochemical data The heats of formation of all the metallic compounds depend upon them, because through them the heat values are referred back to the element. Hence it is highly important for exactness in thermochemistry that these values be determined with great precision.

As a matter of fact, in the past certain difficulties have interfered with the perfection of the measurements. First and foremost among these is the fact that the solution of a metal requires much time, and therefore the always somewhat uncertain correction for cooling in the usual method becomes a serious fraction of the whole rise of temperature. In the second place, the method generally used, namely, the plunging of a weighed sheet of metal into acid, and then withdrawing it, checking the reaction as soon as possible, and determining the amount dissolved by loss in weight, is open to serious criticism. It is impossible that the withdrawal should be so quick as to introduce no error in the results.

The new method of adiabatic calorimetry, recently used at Harvard, seems to be especially suitable for such cases as this, and accordingly, the present investigation concerns itself with the application of this method to the solution of metals in acids This method of calorimetry avoids wholly the cooling correction by surrounding the calorimeter with a jacket, having always precisely the same temperature as the calorimeter itself. The jacket contains an alkali, and as the reaction progresses within the calorimeter, enough acid is added, drop by drop, to this alkali to change its temperature at exactly the same rate as that of the calorimeter proper.

This method overcomes entirely the first fault which exerted an especially detrimental effect upon the early determinations of the heat of solution of metals—this fault being, namely, the large cooling correction, because of the slowness of the process The second difficulty was overcome by another device Instead of dissolving only a part of a large metal sheet or net, we placed the metal in a finely divided condition in a basket, and the reaction was allowed to continue until all which had been placed in the basket was completely dissolved. The calorimetric method allows plenty of time—a slow reaction is as well measured as a quick one. Hence this procedure involves no difficulty, but affords a satisfactory method of overcoming the faults in the doubtful mode of operation previously adopted.

In carrying out experiments by this method, it was found that as the effectiveness increased, another error which also must have affected previous determinations was uncovered In reactions of this kind the solution is not always mixed very thoroughly during the progress of the reaction, and the thermometer does not always fairly represent the average temperature, unless the stirrer is very active. Hence, according to the old method, the cooling correction is not properly calculated, and according to the new method the jacket is not maintained at the right temperature. In either case inaccurate final results will be obtained. Obviously, a correct result is to be hoped for only when the stirring is so active that the temperature is nearly the same throughout the calorimeter. Our experience leads us to believe that early work of this kind did not maintain sufficient equality of temperature. That exceedingly concordant results may be obtained if these precautions are all heeded is shown by the results to be given later.

In brief, this paper presents an account of the highly successful application of the new method of adiabatic calorimetry to one of the most important series among thermochemical data.

Our thanks are due to the Carnegie Institution of Washington, which has granted us generous pecuniary assistance in the prosecution of this work.

Discussion of Earlier Work.

Apparently Thomsen[1] alone, among earlier thermochemists, has measured the heats of solution of most of the metals in acids. We owe much to this eminent investigator, but it is not surprising that his pioneer work, carried out at a time when chemistry was a far less precisely quantitative science than at present, should not have attained a degree of accuracy which is now attainable. A brief description of his method is not out of place. The calorimeter which he used consisted of three concentric cylindrical cans which were insulated from one another by means of air spaces The inner of these cans constituted the calorimeter proper and was made of platinum. The stirrer was a single ring which was moved vertically up and down by mechanical means; since it will be shown in the present work that two such rings vibrating in a similar fashion did not effect thorough mixing, it is quite evident that the stirring which he employed was entirely inadequate The thermometer, which had been carefully standardized, was graduated to tenths and could be read by means of a telescope to 5 one thousandths of one degree—a degree of precision much below the modern standard A single cover on the outside cylinder shielded the apparatus from above and through it the stirrer and thermometer passed The metal was introduced in a sheet or coil of netting, and was withdrawn, washed and dried after a suitable time His results are therefore open to the two main objections, which were emphasized in the introduction, namely, a large cooling correction and an inaccurate method of introducing the metal. Besides these, other sources of error, which must be eliminated from accurate work, were overlooked by him When fine bubbles of gas escape from a solution, they carry away with them small particles of the liquid, and, although the quantity of liquid so carried away is small, yet it is by no means negligible Moreover, his metals were not very pure, being the best he could obtain commercially. The amounts of impurities were determined by analysis, and corrections were applied, entirely ignoring any possible heat effects due to alloying of the metals. The acids mainly used by Thomsen were of two concentrations—$HCl.25H_2O$ and $HCl.50H_2O$. From the results obtained with these acids he calculated the values for acid of the concentration $HCl.200H_2O$. To do this he determined the heat of dilution of the acid from the initial to the final concentration and subtracted the result from the heat of solution of the metal, assuming that the solution of the salt in excess of acid is the same (thermochemically) as its solution in the same quantity of pure water—

---

[1] Thomsen, *Thermochemische Untersuchungen*, Vol. III, page 217. Hess and Favre and Silbermann determined the heats of solution of zinc in hydrochloric and sulphuric acids. Their results have been discussed by Thomsen (*Thermochem. U.*, Vol. III, 273).

an assumption which is plainly hazardous and will be shown later to be incorrect.

A study of one of Thomsen's actual experiments will make clear the error into which he fell as well as indicate the correct method for making this calculation One of the experiments on zinc, in which he dissolved 6 82 grams of zinc in 1248 7 grams of acid of the concentration $HCl.50H_2O$, may be selected[1] The actual conditions of his experiments are accordingly represented by the equation

$$0\ 104Zn + 1\ 332(HCl\ 50H_2O) = \\ 0\ 104H_2 + 0\ 104ZnCl_2 + 1\ 125HCl\ 66\ 6H_2O + 3605\ \text{Cal.},$$

or multiplying by 9 61,

$$Zn + 12\ 80(HCl\ 50H_2O) = H_2 + ZnCl_2(10\ 80HCl)640H_2O + 34{,}620\ \text{Cal.} \quad (1)$$

He then determined the heat of dilution of the acid $HCl.50H_2O$ to $HCl.200H_2O$

$$2(HCl\ 50H_2O) + 300H_2O = 2(HCl\ 200H_2O) + 420\ \text{Cal.}^2 \quad (2)$$

Now by subtracting equation (2) from (1) he claimed to obtain:

$$Zn + 2(HCl\ 200H_2O) = ZnCl_2\ 400H_2O + H_2 + 34{,}200\ \text{Cal.} \quad (3)$$

Evidently this result (equation 3) can only be obtained by a set of reactions similar to the following:

$$\begin{gathered} Zn + 12\ 80(HCl\ 50H_2O) = H_2 + ZnCl_2(10\ 80HCl)640H_2O + x; \\ 12\ 80(HCl\ 50H_2O) + 1920H_2O = 12\ 80(HCl\ 200H_2O) + y, \\ ZnCl_2(10\ 80HCl)640H_2O + 1920\ H_2O - ZnCl_2\ 10\ 80HCl\ 2560H_2O + z; \\ ZnCl_2\ 400H_2O + 10\ 80(HCl\ 200H_2O) = ZnCl_2\ 10\ 80HCl\ 2560H_2O + q; \\ Zn + 2(HCl\ 200H_2O) = ZnCl_2\ 400H_2O + H_2 + x - y + z - q. \end{gathered}$$

That is to say, *all* the acid corresponding to a gram atom of zinc must be diluted, instead of only 2 moles Moreover, the resulting solution of the salt in the excess of acid must be diluted an equivalent amount, and the further change of internal energy, brought about by mixing the pure dilute salt solution (in this case $ZnCl_2\ 400H_2O$) with the proper quantity of acid of equivalent concentration must be determined. It is amazing that no one has ever discovered these errors of logic before. In working out these equations, no account has been taken of the temperature at which the last three reactions should be performed, whether at the initial temperature or final temperature of the experiments for equation (1). This is a matter of considerable importance and will be fully discussed later

Having thus shown the chief causes of inaccuracy in Thomsen's work—which apply with even greater force to earlier experimenters—we may turn to the present series of experiments, and review the various precautions yielding better results. First the preparation of the materials will be discussed, then the calorimetric apparatus, and finally the details of manipulation and the results.

Materials.

The significance of work of this kind depends greatly on the purity of the materials employed. There is, of course, no object in determining accurately the heat of solution of a substance containing unknown impurities in appreciable amount

The materials used in this work were most of them of a high order of purity Where very pure substances were unattainable, the impurities were determined and due allowance for them was made.

Hydrochloric Acid—Three concentrations of hydrochloric acid were used, namely, $HCl\ 8\ 806H_2O$, $HCl\ 20\ 0H_2O$, and $HCl.199\ 8H_2O$. Chemically pure acid was diluted to these concentrations and the exact values were verified by gravimetric analyses in which the chlorine was precipitated with silver nitrate.

Zinc—Two preparations of zinc were employed in the research. The first sample consisted of fine crystals obtained by electrolysis from an ammoniacal zinc sulphate solution A solution containing zinc sulphate had been previously oxidized with chlorine water and the iron precipitated by digestion with freshly made zinc hydroxide. This process was repeated until the precipitate no longer became colored on standing. Zinc sulphate was crystallized from the filtered solution and subsequently recrystallized three times from pure water. The pure salt was dissolved in distilled water, ammonia was distilled into it until the precipitated hydroxide had completely dissolved, and the solution electrolyzed between platinum electrodes under a high current density. In this way very finely divided crystals were obtained, which offered later a large surface to the action of the acid. The metal was removed from the solution by means of a glass instrument resembling a rake, and was preserved under a dilute solution of ammonia. It was washed with dilute ammonia until all zinc salts adhering to it were removed, and immediately afterwards was speedily washed with pure water. As quickly as possible the water was replaced by three washings with alcohol, and this treatment was followed by three more washings with ether.[1] The metal was dried by being placed in a vacuum desiccator containing sulphuric acid.

The surface of the zinc obtained in this fashion, although it appeared very bright, was covered with a very thin film of oxide. This covering was only perceptible from the fact that when thrown upon dry mercury, the metal amalgamated very slowly or not at all; indeed, it could be stirred into the mercury without amalgamating. If, however, the mercury was covered with a dilute solution of ammonia and the zinc thrown upon it, amalgamation proceeded with great rapidity. This fact was utilized to determine the amount of oxide present. A weighed quantity of zinc was amalgamated under a dilute solution of ammonium hydroxide, which was then poured off, neutralized and titrated with a standard potassium ferrocyanide solution. The solution must have contained all the oxide, as the surface of the mercury was perfectly bright. The results show that only a very small part of the metal had been oxidized.

---

[1] The alcohol was purified by being twice distilled from quicklime. The ether was distilled after standing for several days over calcium chloride.

DETERMINATION OF ZINC NOT AMALGAMATED.

	Wt. zinc	Vol. of $K_4Fe(CN)_6$ soln. cc.	Equivalent of zinc oxide. Gram.	Wt. of zinc oxidized in 7.5 grams.
1	1.5	0.14	0.0006	0.0025
2	1.5	0.12	0.0005	0.0020

That is to say, the oxide cannot exceed 0.037 per cent. of the weight taken, hence even if the oxide were insoluble in acid, the error from this source could not exceed this amount. Probably the observed quantity is unduly exaggerated by the solution of some metallic zinc in ammonia, during the act of amalgamation, when electrolytic effects would occur. Therefore 0.03 per cent. is a safe estimate of the combined zinc present in the metal. But a part even of this was probably present as ammoniacal sulphate in solution and not as oxide. When a metal is deposited from a solution, as the zinc crystals had been, it encloses minute drops of the mother liquor, just as do also crystals of most if not all salts;[1] and the quantity of included solution is greater the faster the metal is deposited. The quantity of enclosed mother liquor was determined in the present instance by fusing the metal in a current of dry nitrogen and absorbing the water with phosphorus pentoxide. Blank experiments, in which dry air was passed through the apparatus for a long time, served to eliminate any constant errors of experimentation.

VOLATILE MATERIAL ENCLOSED BY CRYSTALLIZED ZINC.

	Weight of zinc.	Weight gained by pentoxide tube.	Blank.	Weight of volatile matter from zinc.
1	3.00	0.00105	0.0001	0.00095
2	3.00	0.0011	0.0001	0.0010
3	3.00	0.0010	0.0001	0.0009
			Mean,	0.00095

Since the solution used for electrolysis contained about 20 per cent. of zinc sulphate, the total weight of enclosed mother liquor in 3.0 grams of zinc was 0.0012 gram, or 0.04 per cent. of the original weight of metal. This small amount of enclosed mother liquor must have contained about

---

[1] See Richards, *Z. physik. Chem.*, 46, 189 (1903); also Hulett and DeLury, THIS JOURNAL, 30, 1812.

0.1 milligram of zinc, which must have appeared along with the oxidized portion in the amalgamation experiments, and should be subtracted from the quantity there discovered. Otherwise the metal was very pure; a careful qualitative analysis failed to show the presence of any other metal.

The sum total of impurity found in the zinc is thus not over 0 07 per cent., but to apply this correction in full would overstep the mark.

Both zinc oxide and hydroxide, as well as the ammoniacal mother liquor, give out heat when dissolved in acid. The two former yield about two-fifths as much heat as metallic zinc would, and the mother liquor was found to yield about one twelfth as much Hence, considered from a thermochemical point of view, the zinc must have acted as if it contained only about 0 055 per cent of impurity, a correction which is applied in the following pages.

The second sample was Merck's pure zinc ("reagent") in granulated form, which had been pounded into thin sheets on an anvil. Both the hammer and the anvil were carefully cleaned before being used, and the pieces were polished by shaking with sand and alcohol afterwards. This zinc was very pure and contained, as far as careful testing could show, only a very slight trace of iron, which may have been introduced during the process of pounding No attempt was made to determine the amount of iron present, since scarcely a weighable amount of ferric hydroxide was precipitated from seven grams of zinc. No other impurities were found, so that no correction for impurities was made with this material..

Aluminium.—The aluminium used for this work was in the form of a thin foil--the purest that could be obtained on the market. It contained negligible traces of iron and sodium and a small quantity of silicon, which was carefully estimated.

The determination of silicon in a metal of this type is by no means an easy matter. Some of the contaminating element is present in an uncombined form and some combined or alloyed with the metal; the former portion appears as silicon when the metal is dissolved, the latter partly as hydrated silica and partly as hydrogen silicide.[1] The silica is partly precipitated and partly dissolved colloidally. Hence a number of steps have to be taken in order to determine the total amount. In the first place, the aluminium was dissolved in hydrochloric acid and the precipitate collected and ignited in hydrogen. This gave the combined weight of silica and silicon precipitated. Ignition in air then oxidized the silicon to silica, giving a measure of the quantity of the former, and treatment with hydrofluoric acid showed how little of other impurities had been retained by the precipitate. The silica which remained in solution in the acid was found exactly as in a silicate analysis, according to the method recommended by Hillebrand.[1] The silicon which escaped as hydrogen silicide was determined by passing the impure hydrogen from a known weight of the metal through a solution of caustic alkali made from the metal and water in platinum, determining the silica in this solution. Parallel analyses were made with material from several sheets of similar material, the samples showing considerable uniformity. The following tables give the analytical results:

---

[1] Joseph W. Richards.

SILICON IN THE PRECIPITATE.

	Weight of aluminium	Weight of residue after ignition in hydrogen	Weight of residue ignited in air (silica) Milligrams	Per cent of silicon.
1	0.75	....	5.7	0.35
2	0.75	.	5.4	0.33
3	0.75	....	5.1	0.32
4	0.75	0.0030	...	...
5	0.75	0.0030	..	...
		0.0030	5.4	0.34

SILICON IN THE SOLUTION.

Weight of aluminium.	Weight of silica found	Per cent. silicon
0.7500	0.0008	0.050
0.7500	0.0006	0.038
	Average,	0.044

SILICON IN THE GAS.

Weight of aluminium	Weight of silica found.	Per cent silicon.
1.80	0.0008	0.021
1.75	0.0006	0.016
	Average,	0.018

Thus the total weight of the element silicon was found to be 0.40 per cent. of the original weight of the metal taken.

Assuming that the difference between the results of Analyses 1, 2, 3 and 4, 5 gives the weight of oxygen needed to convert uncombined silicon into silica, the silicon present as such in the residue must have been 0.0021 gram.

In computing the effect of the impurity on the heat of reaction, account must be taken of the fact that different forms of silicon have different effects upon the result. According to Berthelot, a gram atom of silicon on being converted into the hydrated dioxide evolves about 180 Calories of heat, whereas it will be seen later that the same weight of aluminium evolves only about 130 Calories. Thus the presence of this silicon causes a larger heat of reaction than the same weight of aluminium. On the other hand, according to Ogier,[1] a gram molecule of hydrogen silicide evolves about 25 Calories when formed from hydrogen and crystalline silicon and 33 Calories when formed from amorphous silicon and hydrogen. When formed from aluminium silicide and hydrochloric acid, the heat of formation would doubtless be somewhat diminished. For the present purpose it is assumed to be about half the value given above, namely, 15 Calories. Making allowance for these facts, it is apparent that for the present purpose the total amount of impurity may be calculated as nearly equal to the amount of silicon found as such, namely, 0.28 per cent.

---

[1] Hillebrand, United States Geological Survey, *Bulletin* 305.

The sodium present was estimated as follows: 0.20 gram of the aluminium foil was dissolved in a platinum dish with pure hydrochloric acid, which gave no test for sodium in the spectroscope; the resulting solution was concentrated to about 1 milliliter and examined in the spectroscope. It was found to be about half as concentrated in sodium as a standard solution which contained 0.02 mg per milliliter. This proves that the quantity of sodium present was less than 0.01 per cent. and may therefore be ignored.

To prepare the metal for use, it was polished on both sides with a mild abrasive; it was then carefully wiped with clean dry cotton and washed with ether to remove any film of grease which may have formed. It was then dried and cut into small pieces with a clean pair of shears.

The metal prepared in this way had a very bright surface and could not have been covered with a film of oxide of more than microscopic thickness. That a film of oxide existed, however, is shown by the fact that the pieces would not amalgamate when thrown on mercury, but if held below the surface of the mercury and scratched, amalgamation slowly occurred. No way was found to estimate the quantity of oxide actually present, because ordinary quantitative analysis could not detect an amount so small. Some idea of the probable quantity, however, may be obtained from the study of the oxidation of electrolytic zinc. The zinc exposed a much greater surface per unit of weight than the aluminium does, and should therefore be oxidized to a greater extent. Now the quantity of zinc oxidized was shown to be less than 0.04 per cent.; nevertheless, when it was thrown on dry mercury and stirred into it, little or no amalgamation took place. As soon as a solution of ammonia was added, however, amalgamation took place almost immediately, and very little zinc was found in the ammonia. It is thus evident that the coating of oxide which will prevent amalgamation is extremely thin; and there is accordingly little likelihood that the film of oxide covering

[1] Ogier, *Ann. chim. phys.* [5], 20, 31, 1880.

the surface of the aluminium was great enough to introduce an appreciable error into the results. In view of these facts the aluminium was assumed to be 99 6 per cent. pure.

Magnesium.—Ribbon—the purest which could be obtained in the market—was used for this work. A careful analysis showed the presence of a small amount of iron and a trace of sodium.

The determination of the iron was made in the following manner: A weighed amount of the metal was dissolved in hydrochloric acid and sufficient ammonium chloride added to prevent the precipitation of magnesium hydroxide. While hot the solution was oxidized with chlorine, and the iron precipitated with ammonia twice in succession, and weighed as oxide The results were as follows:

IRON IN PUREST COMMERCIAL MAGNESIUM.

	Wt. of Mg	Wt of Fe_2O_3	Equivalent wt of iron	Per cent. of iron
1..................	2.50	0 0031	0 0021	0.08
2	2.86	0 0028	0 0020	0.071

Because the iron itself has some heat of solution (about 8 per cent. of that of an equal weight of magnesium), the fraction 0 075 per cent would correspond to about 0 07 per cent. of inactive substance.

The sodium was estimated in the same manner as in the case of aluminium above and was found to be present in about the same quantity. Consequently, no correction for it was necessary.

To prepare the metal for use it was scraped with a knife in order to remove most of its coating of oxide, and afterwards polished with a mild abrasive, which was removed by rubbing with clean dry cotton. The metal then presented a very bright surface and could be kept in a stoppered weighing tube for a long time without tarnishing. There can be no doubt that the surface of the metal was still coated with a very thin film of oxide, because it would not amalgamate when held below the surface of mercury. In view of the experience with zinc, the weight of the oxide probably did not exceed 0 05 per cent. of the weight of the metal. Magnesium, like aluminium, is far more active than zinc, and therefore should be more easily oxidized; but the more compact form probably about compensated in the present case for the greater activity, because less surface was exposed with either aluminium or magnesium than with zinc.

As an outcome of these experiments, the magnesium was assumed to have a purity of 99.9 per cent. with an uncertainty probably not exceeding 0.05 per cent. in either direction.

Cadmium.—The cadmium used for this work was prepared electrolytically from cadmium sulphate which had been twice recrystallized from pure water, in precisely the same way as the zinc. The finely divided crystals were washed with dilute ammonia solution until free from cadmium salt, then with water and finally with alcohol and ether, as before described, and were dried in a vacuum over concentrated sulphuric acid.

Since cadmium is a less active metal than zinc it should be less oxidized when prepared in the same manner. The quantity of zinc oxidized was found to be too small to introduce any serious error into the results. Therefore, the quantity of cadmium oxidized was not determined.

The mother liquor enclosed by the crystals of the metal was found to be considerable in amount, for its determination the method used in the case of zinc was employed.

VOLATILE MATERIAL ENCLOSED BY CRYSTALLIZED CADMIUM

	Weight of cadmium	Weight gained by drying tube	Blank	Weight volatile matter from cadmium
1	5.00	0.00535	0.0001	0.00525
2	5.00	0.00510	0.0001	0.0050
3	5.00	0.0051	0.0001	0.0050
4	5.00	0.0048	0.0001	0.0047
			Average,	0.00499

Since the electrolysis was conducted with a twenty-five per cent. solution, the corrected weight of mother liquor was 0.00665 gram; that is to say, the weight of enclosed mother liquor was 0.13 per cent. of the original weight of metal. The heat produced by the neutralization of this ammoniacal mother liquor was about one sixth of the quantity which would be produced by the solution of an equal weight of cadmium; hence the correction to the weight for thermochemical purposes would be 0.11 per cent. As no other impurity was found in the cadmium, the metal was calculated as having a purity of 99.9 per cent.

Iron.--The iron used in this work was obtained from four different sources.[1] They will be spoken of as Samples A, B, C and D.

Sample A was iron reduced by hydrogen obtained from Kahlbaum and was undoubtedly very pure. It was prepared for use by being freshly reduced in hydrogen, at a very moderate temperature. Ignition at a very high temperature would have diminished the surface and therefore the speed of subsequent solution, by causing the particles to cohere more closely.

---

[1] A fifth sample was furnished by Professor C. F. Burgess, of the University of Wisconsin. It was prepared electrolytically and contained considerable hydrogen. The rate of solution is undoubtedly greatly influenced by the quantity of hydrogen present. When first obtained it dissolved at a rate comparable with the other samples. After having been kept for a year, however, it dissolved so slowly that no results could be obtained with it. The same effect was produced by heating it strongly in a vacuum for a considerable length of time.

We wish to express our thanks to Professor Burgess for his courtesy in supplying this sample.

Sample B was similar in appearance; it was prepared from ferric nitrate which had been recrystallized four times from a strong nitric acid solution. The pure ferric nitrate had been heated in a platinum dish at a low temperature until converted to the dark red basic nitrate. This was then removed, finely ground,[1] and afterwards strongly heated in a platinum dish until completely converted to the oxide. The ferric oxide was placed in a porcelain boat and reduced at as low a temperature as possible in a current of pure hydrogen.[2]

Sample C was made by electrolysis of ferrous sulphate solution, to which had been added a small amount of ammonium chloride. The electrodes were of platinum, and, as soon as a thin layer of iron had formed, it was removed and kept under a dilute solution of hydrochloric acid. In this way thin plates of the metal were obtained, which exposed a considerable surface to the action of the acid The preparation was finally washed with water and reduced in a current of hydrogen.

Sample D was prepared by the electrolysis of a solution of ferrous chloride. It was treated in the same manner as Sample C.

Of these samples, those reduced from pure oxide in hydrogen were undoubtedly the purest; these were essentially free from impurity. The electrolytic iron probably contained less than 0 1 per cent. of impurity derived from the electrolyte.

Apparatus.

The Calorimeter.—This work, involving the purest materials just described, was carried out with the aid of the adiabatic calorimeter, of which a vertical section is shown in the figure. The form of environment first employed consisted of two concentric cylindrical vessels of copper and a cover. The smaller cylinder, within which was placed the calorimeter proper, was secured inside of the larger one on legs made of hollow brass tubes about eight or ten centimeters in length. The space between the copper cylinders was filled with a solution of crude caustic soda, the liquid being allowed to come as near the top of the vessels as possible without danger of overflowing when stirred vigorously. The cover was a cylindrical vessel, also of copper, about ten centimeters in height, of such a diameter that it fitted easily inside the smaller cylinder, and projecting therein to such a depth that it was only two or three millimeters from the top of the calorimeter can. Four vertical brass tubes were soldered into the bottom of the cover, through which passed the stirrer, thermometer, and rod from which the basket containing the metal under treatment was suspended. The cover also was filled with the crude alkaline solution, so that the calorimetric space was surrounded on all sides by an insulating layer of liquid about a decimeter thick, which could be kept by means of added acid so nearly at the same temperature as the calorimeter itself that the exchange of heat between them was negligible. The narrow annular space between the sides of the cover and the top of the inner cylinder was stopped by means of a rubber washer which was fastened to the sides of the cover. If this space was not closed, the current of air circulating through it was found to cause evaporation from the calorimetric vessel, and hence accidental cooling. The liquid in the large outside cylinder jacket was very vigorously stirred by means of a triple-screw propeller—a method which was found to be exceedingly efficient. The cover was stirred by means of a perforated copper disk which moved up and down at the same rate as the stirrer in the calorimeter proper. This method of stirring is not so efficient as the propeller, but was found to be adequate.

---

[1] An iron mortar, according to Hempel, is obviously an ideal tool for this purpose.

[2] Richards and Baxter, *Proc. Am. Acad.*, 35, 253 (1900). *Z. anorg. Chem.*, 23, 245 (1900).

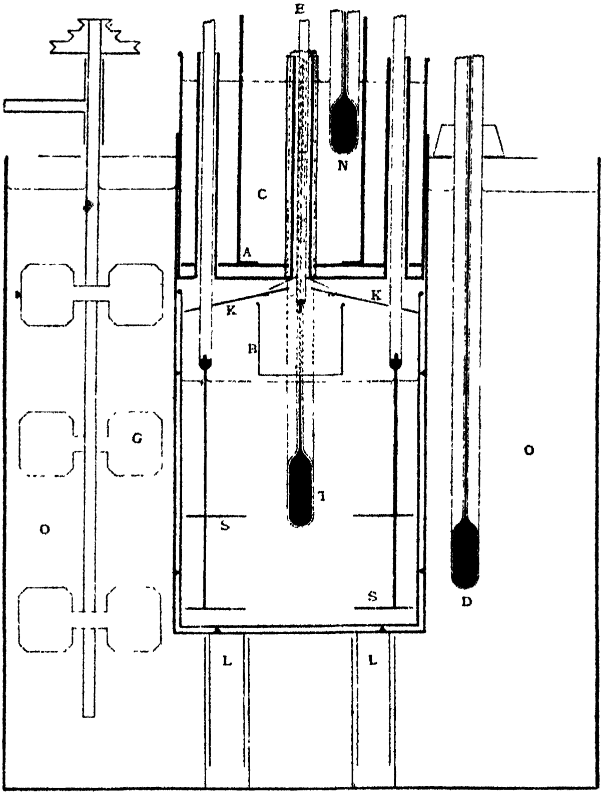

Fig. 1.

A few experiments at the close of the research were conducted by means of a modification of this calorimeter—a modification which on the whole proved so satisfactory that it will be used in future work of this kind. This modification had already been used in principle in the work of Richards and Forbes in "Energy Changes Involved in the Dilution of Zinc and Cadmium Amalgams.[1] In this apparatus the cover of the environing bath was dispensed with, and the calorimeter proper was enclosed in a sealed can of metal wholly below the surface of the liquid in the large copper pail constituting the lower jacket. The tubes for the thermometer and other apparatus were attached to the lid of the sealed can, and the latter was wholly submerged. Thus the reaction was conducted in a sort of submarine vessel, having only a few tubes above the water level.

At first we feared that the cover would be difficult to make water-tight, and that the manipulation would be complicated by the firm attachment of the lid of the calorimeter can, but, as a matter of fact, these difficulties were found not to be prohibitory. By pressing a large flat elastic rubber washer between the top of the can and the lid, and holding the latter down by suitable clamp screws, a perfectly water-tight joint may be had, if the metal surfaces are smooth.

The best arrangement of these details has been described in a paper by R. H. Jesse, Jr., and one of us,[2] in whose investigation the apparatus was subjected to a much more thorough test

A submerged vessel of this kind was found to provide altogether the best means of accomplishing the desired result. With this apparatus the experimenter has only one vessel to adjust at the temperature of the calorimeter inside, and the strain upon him is therefore distinctly less than when the lid also must be specially adjusted. The final results given by the calorimeter are exactly identical with those afforded by the other, as may be seen from the inspection of the results on zinc. The identity with the results obtained with the two sets of instruments is a valuable confirmation of each.

A cylindrical platinum can was used as the calorimeter proper. Its capacity was about 1.2 liters, and it weighed 177.25 grams. It was of such a size that it fitted loosely inside the inner copper cylinder of either form of adiabatic jacket, leaving an air space of about two or three millimeters in width on all sides. From the copper cylinder it was thermally insulated by means of triangular pieces of cork which were made as small as possible and placed with the apex against the calorimeter can. These pieces of cork were so small that their heat capacity was entirely negligible.

Thermometers.—Beckmann thermometers, graduated directly to hundredths and readily estimated to thousandths by means of a lens, were used for determining the temperature change of the calorimeter. They were very carefully standardized by comparison with two international standards, calibrated with the greatest care in Paris.[1] The comparisons were made while the Beckmann thermometers were subjected to precisely the conditions of exposed column, etc., to which they were submitted during the calorimetric determination, so that the corrections could be applied with strict consistency. The cruder thermometers used in the jacket and cover were graduated to twentieths and could be easily estimated to hundredths. They were compared with the standardized thermometers throughout the part of the scale used, and all were set so as to read together within two or three hundredths of a degree.

---

[2] THIS JOURNAL, 32, 268.

Stirrers.—In the early parts of the work a stirrer made from round glass rods bent and fused together was used inside of the calorimeter can. The surface exposed by such a system of rods is small, and consequently the stirrer would have to be driven at a high speed in order to produce very complete mixing. As will be shown later, this stirrer was not able, when running at a rate of about one hundred strokes per minute, to stir efficiently the calorimetric liquid. Accordingly, a stirrer made from sheet platinum and offering as great a surface as possible was used in all the final results. The diagram shows clearly the manner of its construction. It consisted of two rings, two centimeters in width, perforated with holes at regular intervals. These rings were connected by rods of platinum, which projected above the surface of the liquid. The rods were sealed into glass tubes which passed through the cover and were connected to the driving mechanism.

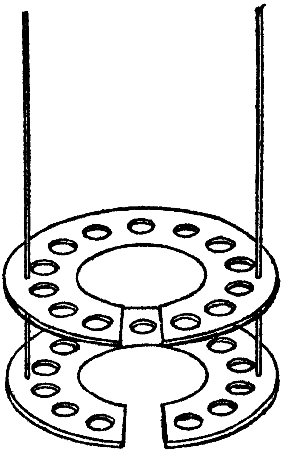

Fig. 2.

The Platinum Basket.—A cylindrical basket, about 4 cm. in diameter and 3 cm. high, made from platinum gauze, was used to support the metal to be dissolved. As the metal was sometimes very finely divided, it occasionally sifted through this gauze, and began to dissolve before its time. In order to prevent this cause of inaccuracy, a cap of platinum foil was sprung over the bottom of the basket outside, and just before the basket was lowered into the acid this cap was pushed off by means of a suitable device and allowed to fall to the bottom of the calorimeter. The basket itself was held by means of a stout hook of platinum wire, attached to the glass tube which ran through the copper tube attached to the center of the cover.

---

[1] These standards are described by Richards and Wells, *Proc. Am. Acad.*, 38, 434 (1902); *Z. physik. Chem.*, 43, 467 (1902).

Apparatus for Preventing Loss of Drops.—In the early experiments a considerable amount of the liquid, as much sometimes as one-half of a gram, was carried away in the form of drops by the escaping gas. These drops resulted, of course, from the bursting of the small bubbles as they rose to the surface. This is a familiar phenomenon whenever a gas escapes from a boiling or effervescing liquid. Several devices were tried to prevent this cause of inaccuracy An inverted watch glass perforated in the center, placed over the top of the basket, served only partially to solve the difficulty. Next, a miniature bell-jar of very thin glass, fitting over the basket, and provided with a fine delivery tube above, just dipping under the liquid, was tested. This device collected the larger bubbles, but the smaller were driven throughout the liquid by means of the violent stirring and escaped from under the bell. Clearly some arrangement was necessary which should include in its scope practically all of the contents of the calorimeter, and, as a matter of fact, the difficulty was entirely overcome by means of such an apparatus as is shown in the accompanying diagram. A large flat cone with a diameter almost as great as the internal diameter of the platinum calorimeter, and an altitude of not over 3 cm , was placed over the basket At the apex a hole was cut to accommodate the rod which carried the basket. The cone was attached to the rod, leaving a space around it for the escape of the hydrogen, and a second small cone fitting closely to the rod was fastened a few millimeters above the first, in order to cover the opening provided for the escape of the gas The fine bubbles of hydrogen slowly ran up the lower sides of the larger cone and collected in larger bubbles under the surface of the smaller cone, and from the edge of the smaller cone the gas bubbled through the liquid in a well-ordered manner, giving a minimum projection of the solution in the form of drops. As the heat capacity of the platinum cones was small and easily determined, this device introduced no error, and at the same time eliminated the difficulty in question. It was used in all the later experiments. Only Series 1, involving the solution of zinc, suffered from loss by the projection of drops, and to this a small correction was applied for the liquid which had escaped being warmed by the reaction in this fashion.

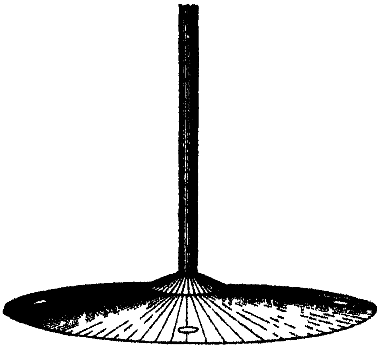

Fig 3.

The Efficiency of Stirring.

It has been stated that previous work of others, as well as our own early experiments, were probably in error on account of inadequate stirring.[1] The facts on which we base this statement will now be presented. In the experiments whose results are tabulated below, three different thermometers were used, all of which had been carefully standardized. No. 1 reached nearly to the bottom of the calorimeter, No. 2 about midway, and No. 3 only a short distance below the surface of the liquid. These three thermometers were used to measure the heat of solution of a definite amount of zinc in dilute hydrochloric acid. The heat capacity of the system was the same in each case and the same weight of metal was dissolved. The liquid was in each case stirred by the inadequate glass stirrer mentioned before. The corrected temperature rise as observed with the three thermometers is recorded in each case.

TEMPERATURE RISE AT DIFFERENT DEPTHS WITH INADEQUATE STIRRING.

	Thermometer No. 1	Thermometer No. 2	Thermometer No. 3
	4.151	4.213	4.225
	4.149	4.210	..
	4.151	4.207	.
	4.150		.
	4.149		....
Mean,	4.150	4.210	4.225

The results with thermometer No. 2 are 1.45 per cent. and that with No. 3 1.8 per cent. higher than those with No. 1, that is to say, the liquid at the top remained consistently warmer than that at the bottom during the experiment, which is exactly what would be expected if the stirring were inefficient. When the thermometer bulb was at the bottom, the temperature indicated by it was undoubtedly too low throughout the whole progress of the experiment. This caused the jacket to be kept at too low a temperature and the reacting system must have lost heat to the surroundings. A parallel error would have come from this cause if the Regnault-Pfaundler method had been used to compute the cooling correction, and has probably entered into much similar work in the past.

After the discovery of this unexpected source of error, the glass stirrer was entirely rejected, and the far more efficient stirrer of platinum alone was used. Experiments were then instituted to discover how rapidly this must be operated in order to commingle adequately the reacting substances. Forty strokes per minute still left an error of over 0.2 per cent., while sixty strokes per minute gave adequate mixing, as judged from the constancy of the outcome. This may be given here, as a contrast to the results in the preceding table. The following results were obtained with two different rates of stirring and two different thermometers. The first thermometer reached about midway, and the second nearly to the bottom of the calorimeter. The heat generated by stirring was determined and in each case the appropriate correction was applied. The values for this correction will be given later. In each case 7.500 grams of zinc were dissolved in 941 4 grams of dilute acid. The nine experiments are arranged below in two ways—first classified as to speed of stirring (Series I and II) and then classified according to the thermometer used (Series III and IV).

---

[1] W. P. White has independently come to the same conclusion, *Phys. Rev.* (1908).

TEMPERATURE RISE AT DIFFERENT DEPTHS WITH ADEQUATE STIRRING.

	Series I. 110 strokes per minute	Series II 60 strokes per minute	Series III. Thermometer 1.	Series IV Thermometer 2
	4.247°	4 246°	4 247°	4 244°
	4.245°	4.245°	4.245°	4.247°
	4.244°	....	4.246°	4.246°
	4.246°	...	4.247°	....
	4.247°	..	4 246°	....
	4.246°	.	4.245°	...
	4.247°	...	....	...
Aver.,	4.2460°	4 2455°	4.2460°	4.2457°

These results prove conclusively that with the rates of stirring employed the mixing was very complete and the liquid was uniformly warmed throughout the reaction, for the differences between each average and the general average are of the same order as the probable error of each. In other words, the results are identical within the limits of experimentation. Hence the rate of sixty strokes per minute was adequate, with our efficient stirrer, to accomplish the desired result

Correction for Heat Evolved by Stirring.

The rate of stirring required for these experiments was sufficient to cause considerable heat to be generated. This quantity must obviously be determined for each liquid used. In the adiabatic calorimeter the determination may be made with great ease and precision.

When the acid solution ($HCl.20H_2O$) was stirred at the highest rate employed, *i. e.*, 110 strokes per minute, the following results were obtained:

	Time. Min	Temperature rise	Average rise per minute
1.	20	0.025°	0.00124°
2.	15	0.018°	0.00120°
3.	30	0.038°	0.00125°
Total.	65	0.081°	0.00123°

When the more concentrated acid ($HCl.8.808H_2O$) was stirred at the same rate, a rise of 0.054° was caused in 30 minutes, at the rate of 0.0018° per minute. Thus the denser liquid caused a greater stirring correction, partly because of its lower heat capacity.

With the same acids and the slower rate of stirring (60 strokes per minute) the correction assumed the following much smaller values;

Acid.	Time. Min.	Temperature rise.	Average rise per minute.
$\mathrm{HCl.8.808H_2O}$	60	0.009°	0.00015°
$\mathrm{HCl.20H_2O}$	40	0.006°	0.00014°
$\mathrm{HCl.20H_2O}$	60	0.008°	0.00014°

The value for the least concentrated acid ($\mathrm{HCl.200H_2O}$) was not determined, but since the heat capacity of the system in that case was about 10 per cent. greater than that with the acid ($\mathrm{HCl.20H_2O}$) the stirring correction was undoubtedly about 0 007° in an hour. It is interesting to note that when the rate of stirring is doubled the heat generated is increased about tenfold. This is in approximate agreement with experience of naval engineers in calculating the quantity of coal necessary to drive ships at sea.

Possible Error Caused by Heat Exchange with Surroundings.

If the environment of the calorimeter is kept *exactly* at the temperature of the calorimeter, no heat exchange can take place. Since perfect exactness in this adjustment is not often to be attained, we investigated with care the possible effect of slight imperfections in the adjustments of temperatures We had expected to find nearly equal effect in the two opposite directions of cooling and warming, but somewhat to our surprise, this expectation was not fulfilled. When the temperature of the jacket was maintained 0.1° higher than that inside the calorimeter for a period of twenty minutes, only a barely appreciable change was observed in the temperature inside the calorimeter; but when it was 0.1° lower a very noticeable cooling effect is manifested. This latter effect was proba- due to a distillation of the water out from the calorimeter and subse- ent condensation on the copper walls of the inside of the jacket. Dis- lation into the calorimeter when the outside jacket was warmer could ot take place, because the calorimeter space is entirely protected from he outside air, and there was then no source of moisture to draw upon. t is possible that evaporation into the slight current of air drawn through the tubes also contributed to the effect.

This observation, which was first made by one of us in collaboration with Dr. A. W. Rowe, is so important in its bearing upon calorimetric work in general that a typical series of results should be given. In the first place, the outer jacket was adjusted at precisely the same temperature as the calorimeter, and the small correction for the stirring of the latter was noted. The jacket was then kept at a temperature just 0.1° above the calorimeter, and the further progress of the temperature was carefully observed. Two rates of stirring were employed in two different experiments, one very active, and the other somewhat less so. Having thus determined the effect of having the jacket too hot, the same experiment was repeated with the opposite disturbing cause—the jacket around the calorimeter was kept 0 1° too cool. The results are recorded in the table below; in each case the test lasted forty minutes:

EFFECT OF MAINTAINING JACKET AT TOO HIGH OR TOO LOW A TEMPERATURE.

Rate of stirring	Correction for stirring for time named	Excess of jacket temperature	Change in calorimetric temperature	Effect to be measured.
Rapid	0.006°	+0 1°	+0.008°	+0.002°
Slow	0.002°	+0.1°	+0 004°	+0 002°
Rapid	0.006°	—0 1°	—0 018°	—0.024°
Slow	0 002°	—0.1°	—0 021°	—0.023°

Thus each set of experiments is entirely consistent within itself; clearly, the exposure of the calorimeter to an environment warmer by 0 1° only alters the temperature of the former by 0 001° in twenty minutes; but if the difference of temperature is in the opposite direction, the cooling correction is more than ten times as great

These experiments demonstrate the faultiness of Rumford's method of correcting for cooling by starting a reaction as much below the temperature of the room as the process concludes above it. Evidently, if the calorimeter is in a closed metal vessel like ours, the gain in heat during the first part of the process will be only about one-tenth as great as the loss during the latter part, and the total observed evolution of heat will be much too small. Because Rumford's method has usually been used in the case of the solution of metals in acids, the discovery of this source of error is especially pertinent to the present work.

After the discovery of these circumstances the temperature in the jacket is always kept one or two hundredths of a degree above rather than a little below that in the calorimeter. There was no difficulty in keeping the temperature of the jacket within 0 1° of that of the calorimeter throughout an experiment, and for the greater part of the time the difference was 0 05° or less, hence it is evident that no error is introduced in the present case from this source. The stirring correction was determined under precisely similar conditions, and hence could be consistently applied.

Correction for Evaporation of Acid.

The hydrogen evolved during these reactions is saturated with the vapor of the solution in which it is produced. Others have considered it as saturated with aqueous vapor only, and the correction has been calculated, assuming that the heat of evaporation of water was the same from an acid solution as from pure water. We thought it worth while to test this assumption by experiment, and the following account of the test may well be given here following that of the other small corrections, although the application of the results is not in place until the completion of the chief part of the experiment.

The test was conducted by bubbling dry air through the usual amounts of the various solutions concerned, kept at the average temperature of the main experiment, and noting the fall of temperature actually produced per liter of air.[1]

The details of experimentation were as follows: Into an eight-liter roughly graduated bottle was run a stream of water, thus forcing the imprisoned air through the driers, which consisted of two sulphuric acid wash bottles and a phosphorus pentoxide tube. The air subsequently passed through a long coil of lead pipe in the calorimeter and a shorter coil in the cover, to ensure that the air should be at the same temperature as the liquid inside. It then passed through a central tube of the cover and bubbled through the liquid inside the calorimeter. In order to prevent the absorption or emission of an appreciable amount of heat by the air in passing through that very small part of the tube exposed to the air of the room, the latter was kept as near the temperature of the experiment as possible

A thermometer was placed in the bottle to measure the temperature of the air at the beginning of the experiment, and a mercury gauge also was inserted to indicate the difference in pressure. The volume of the air was corrected to standard conditions. In order to test the accuracy

---

[1] Dry hydrogen would perhaps have been better, but we assumed that the same quantity would evaporate into each gas.

of the method, pure water was at first experimented upon, and the results are given in the table above, with those concerning the acid. The table explains itself; attention is called to the fact that the last column contains the essential outcome of the experiment, namely the cooling effect produced on the given calorimetric system by evaporation into a single liter of dry gas. The mean temperature of the other experiment (18°) was chosen for these experiments.

Evidently the cooling effect produced in pure water and the two most dilute solutions of hydrochloric acid is almost the same, allowing for the somewhat different heat capacities of the two systems, as indeed one would expect; but with the most concentrated acid the cooling effect is very much less in proportion. On comparing the actually observed cooling effects with those calculated from the tension and latent heat of pure aqueous vapor at the appropriate temperatures (0.0098°, 0.0099°, 0.0109° and 0.0121°, respectively), it is apparent that in every case except the last the method gives a higher result than the theoretical one by an amount averaging about 5 per cent. This is undoubtedly in part due to the cooling effect produced by the expansion of the gas, as it rises through the liquid, but this effect is not large enough to account for the whole difference. The discovery of the cause of irregularity would have constituted a research in itself, and as an accuracy of 5 per cent. was enough for our present purpose, the matter was not followed further at this time. The diminished cooling effect in the most concentrated acid is the important outcome of this series of experiments.

The Heat of Solution of Metals in Concentrated Acids.

The heats of solution of the metals, zinc, aluminium, magnesium, cadmium, and iron have all been determined in the course of the present research, and so also have the heats of dilution of the liquid factors and products concerned, in order that all the results might be reduced to the usual dilution with 200 molecules of water. The present section deals with the determination of the heat of solution.

In each case (except a few of the experiments with magnesium) enough metal was used to cause in the calorimetric system employed in its particular case, a change of temperature of about 4°, and in each case the final temperature was not far from 20°, the range being from the neighborhood of 16° to that of 20°. Because of the widely different speeds of reaction with these five different metals, different concentrations of acid were needed in the different cases in order that the reaction should neither be too rapid nor too slow in rate. For zinc and aluminium the concentration $HCl.20.0H_2O$ was used; for the magnesium a solution in ten times as much water ($HCl.199.8H_2O$); and for cadmium and iron, which dissolved much more slowly, the far more concentrated solution, $HCl.8.808H_2O$ was needed, and even this acted with extreme slowness.

Stronger solutions were not used because of the large amount of acid which evaporates from them, and because of the excessive complication introduced by the great heat of dilution. Hydrochloric acid was used rather than sulphuric because there is no danger in the case of hydrochloric acid of the existence of such side reactions as are caused by the partial reduction of sulphuric acid

The method of experiment was essentially the same in the case of each metal. A weighed quantity of acid was placed in the calorimeter and a weighed quantity of metal in the basket. The whole apparatus was then assembled in the manner shown in the diagram (Fig. 1). The temperature of the jacket and cover were adjusted to that of the calorimeter, and the whole was allowed to stand for ten or fifteen minutes to make sure that the basket and metal had reached the temperature of their surroundings The stirrers were put in motion, and the thermometer was read until a constant reading was obtained for several minutes. The basket was then lowered into the acid and the rise of temperature inside equaled in the jacket by running concentrated sulphuric acid from the burettes. These burettes were graduated in tenths of a degree—that is to say, they indicated the amount of acid necessary to raise the alkaline solution in the jacket by successive increments one-tenth of one degree. The reaction of course became slower and slower, as it proceeded, and finally, when the temperature rise settled down to the regular rise due to the known correction for the stirring, the reaction was known to be at an end, and the final temperature readings were made.

As will be seen from the table below, the time necessary varied greatly in the different cases, depending in part upon the accidental arrangement of the pieces of metals in the basket and in part upon their chemical nature. In the cases of cadmium and iron, the reactions were so deliberate that it was necessary to introduce platinum chloride into the solution in order to catalyze the reaction. This resulted, of course, in a side reaction, involving the deposition of a small amount of platinum and the corresponding evolution of slightly too much heat. The platinum so deposited was collected by filtration and was weighed at the close of the experiment. The correction was applied duly in each case, and amounted on the average to somewhat less than four one-thousandths of a degree in the case of iron, the average amount of platinum precipitated in each case being about 8 milligrams in the case of cadmium and 10 milligrams in the case of iron. The equations necessary for calculating the reaction for the platinum precipitated by cadmium are as follows:

$$\mathrm{Pt} + 2\mathrm{Cl}_2 + 2\mathrm{HCl\ aq} = \mathrm{H_2PtCl_6\ aq} + 84.6\ \mathrm{Cal};^{1}$$

---

[1] Thomsen, *Thermochemische Untersuchungen*, 3, 431 (1883).

$$2Cd + 2Cl_2 + aq = 2CdCl_2\,aq + 192.5\text{ Cal};^{1}$$

$$2Cd + 2H_2PtCl_6\,aq = 2CdCl_2\,aq + Pt + 2HCl\,aq + 107.9\text{ Cal.}$$

By subtracting from this the value for the reaction $2Cd + 4HCl\,aq = 2CdCl_2\,aq + 2H_2 + 35.0$ Cal., we obtain the quantity of heat which is introduced by the action of one gram-atom of platinum, *i. e.*, 73 Cal. The correction was calculated by means of the following formula:

$\beta = 73 \times W/M \times K$, where β = correction in thousandths of one degree, W = weight of platinum found, M = atomic weight of platinum, and K = heat capacity of system.

The equations used in calculating the correction for platinum precipitated by iron are as follows:

$$Pt + 2Cl_2 + 2HCl\,aq = H_2PtCl_6\,aq + 84.6\text{ Cal.}$$

$$2Fe + 2Cl_2 + Aq = FeCl_3\,aq + 199.9\text{ Cal.}^{2}$$

$$2Fe + H_2PtCl\,aq = 2FeCl_2\,aq + Pt + 2HCl\,aq + 115.3\text{ Cal.}$$

Subtracting from this the heat of solution of two gram-atoms of iron:

$$2Fe + 4HCl\,aq = 2FeCl_2\,aq + 2H_2 + 42,$$

gives the output of heat (73 Cal.) for one gram atom of platinum. The correction is calculated by means of the equation already given, the evolution of heat being essentially identical in the two cases. A portion of the liquid was removed with a pipette immediately at the close of the experiment and tested with sulphocyanate; no trace of oxidation was observed.

The heat capacities of the various factors in the reaction, including the calorimetric apparatus which was warmed by it, were computed from the weights of the several parts. By far the most important portion of the heat capacity consists of the acid solution, and accordingly, especially accurate determinations were needed. We are greatly indebted to Dr. A. W. Rowe for his kindness in determining the specific heats of the three acids used by us between the temperatures of 16° and 20°, by the new method now in use in Harvard University.[3] The specific heats of the three acids employed were respectively as follows: the weakest solution ($HCl.199.8H_2O$) 0.9814, the solution of medium concentration ($HCl.20.0H_2O$) 0.8486, the most concentrated solution ($HCl.8.808H_2O$), 0.7312, compared with water over the same range, 16 to 20°. The specific heats of the various pieces of apparatus (with the exception of the thermometer) and the metal dissolved are given with sufficient accuracy by previous determinations made by others and were taken as follows:

Zn	0.098	Fe	0.112
Al	0.202	Pt	0.032
Mg	0.245	Glass	0.186
Cd	0.054		

The thermometer was estimated by the method given in Ostwald-Luther's well-known "Handbuch."[1] The following table gives the heat capacities of the various systems concerned. The two series of experiments with zinc differ only in that the first series was conducted with the inadequate glass bell for preventing the projection of drops of liquid. Accordingly the specific heat of 25 grams of glass had to be included in the system, and a correction of one quarter of a gram had to be made for the liquid lost by projected drops of liquid. The amount of this loss was found to be on the average about one half a gram, and one-half of this quantity was taken, because the loss was gradual from the beginning to the end of the experiment. In the second series with zinc and all the other series with other metals the platinum cone, weighing about 9 grams, replaced the inadequate glass bell, and no important amount of acid was lost by the projection of drops. The differences in the heat capacities of the acids are due to the different specific heats and weights taken. The system included also half of the air in the space surrounding the calorimeter by means of which the latter was insulated from the inner cylinder of the jacket. The volume of air was calculated to be 160 cubic centimeters, which at constant pressure has a heat capacity of 0.22 mayer. Since the total heat capacity of the system was always over 3000 mayers, this quantity may safely be neglected, as being beyond the accuracy of the measurement.

In the first three experiments with zinc, 941.2 grams of acid were used; in each of the other experiments with zinc and aluminium the weight of acid was 941.4 grams. In the case of magnesium, 904.0 grams of the more dilute acid were employed, while the most concentrated acid used in the experiments with cadmium and iron, weighed 983.0 grams in each trial. Here is given a table showing the heat capacities of the several systems, calculated from the foregoing data.

	First zinc.	Second zinc.	Aluminium	Magnesium.	Cadmium	Iron.
Platinum	8.4	8.7	8.7	8.7	8.7	8.7
Glass	4.7	...	..	...	...	...

Metal	0.7	0.7	0.2	0.2	0.8	1.0
Thermometer	1.4	1.4	1.4	1.4	1.4	1.4
Total in Cal/t°	813.9	809.7	809.2	897.5	729.7	729.9
Total in mayers	3404.	3386.	3384.	3753.	3053.	3053.

---

[1] Ostwald-Luther, "Hand- und Hülfsbuch zur Ausführung physikochemischer Messungen," 2nd edition (1902).

With successive preparations of each of these systems a number of experiments on the heat of solution of metals in acids were made. More experiments were made with zinc than with the other elements for three reasons: in the first place because the first method which had been used was not wholly satisfactory, in the next place because experience was at that time being gained concerning all the details of the manipulation, and finally because two entirely different samples of zinc were tested.

The volume of hydrogen evolved in each of these experiments under standard conditions was calculated, and multiplied by the average fall in temperature per liter of gas passed through each calorimeter full of each acid, according to the table already given on page 451.

A sample experiment showing the general method is given below.

The Heat of Solution of Zinc.

7 5 grams of electrolytic zinc were used, being equivalent, according to the analysis, to 7 496 grams of pure zinc. The calorimeter contained 941.4 grams of acid or 2.372 moles of hydrogen chloride. The temperature of the air was 18°. This is the experiment number 6 below.

Time.	Reading of thermometer in calorimeter	Reading of thermometer in the jacket reduced to the same standard as the calorimeter.	Reading of the thermometer in the calorimeter corrected for errors of calibration.
0	0.830	0.82	0.808
1	0.830	0 82	0 808
2	0.830	0 85	0.808
3	0.830	0.85	0.808
20	5.010	5.02	5.027
22	5.031	5 04	5.049
23	5.033	5.08	5.051
24	5 035	5.09	5.053
25	5.035	5 05	5.053
26	5.035	5 05	5.05
27	5.036	5.04	5.054
28	5.036	5 02	5.054

Thus the difference between the corrected readings of the thermometer was 4.246. To this must be added 0.002° for the correction for the thread of the thermometer exposed to the somewhat cooler air of the room, and from the results must be subtracted 0 003° for the heat added by the stirring, the slower rate having been used in this experiment. The final temperature attained was 19.87°. The volume of hydrogen evolved, reduced to standard conditions, was 2.57 liters, which number being multiplied by the cooling effect of one liter of gas under the same conditions (0 0117°), gives 0.030°, the correction to be applied for the vaporization of the solution. The corrected rise of temperature is 4 275° in a heat capacity of 809.7. Multiplying these two quantities together, the heat evolved in the experiment, expressed in 18°-Calories, is found to be 3461 Calories. A table containing the data for all the metals follows:

									Average,	3312

The table explains itself, the five metals, zinc, aluminium, magnesium, cadmium, and iron being named in the order in which they were investigated in the second column, and the various essential data concerning the several experiments being given in the following columns. The last column of all contains the products of the several parts of numbers in the two preceding columns and gives the various amounts of heat evolved in each of the several experiments. These values are those which would be manifested by an isothermal reaction conducted at the final temperature attained in each case, 20° ±, because the heat capacities of the factors were used in calculating the results.[1]

Comparison of the results in the last column of this table shows that the calorimetric method had been brought to a high degree of constancy, because the agreement between the several results for each reaction is excellent; that is to say, the probable error of each of these averages is small, in so far as the actual errors of experimentation are concerned. Except in the case of cadmium, which is the least satisfactory, the maximum difference from the mean of the individual determinations is very little over one-twentieth of one per cent., and even in the case of cadmium it is only about one-tenth of one per cent. The probable error calculated according to the method of least squares is accordingly much less than this. Evidently we have here a list of data far more accurate than anything of the kind which has been published before. For example, Thomsen's results for zinc, with which he made more experiments than in the other cases, vary from 34.04 to 34.69 Calories—an extreme variation of nearly 2 per cent., or a deviation from the mean of about 1 per cent. on each side. This is a grade of accuracy over tenfold less than that shown by the present series of determinations. The average final results are brought together in the following table, together with the same calculated upon the basis of a gram-atom of metal instead of the small amount which happened to be used in the experiment. The latter are given both in terms of large Calories (18°) and kilojoules, the factor 4.182 being employed for the computation of kilojoules. The range over which the specific heats were measured being 16–20°, the Calorie is taken at 18°.

HEAT OF SOLUTION OF THE METALS IN AN EXCESS OF HYDROCHLORIC ACID AT 20°.

Metal.	Concentration of acid.	Weight of metal dissolved	Heat evolved in experiment (in small Calories).	Atomic weights	Heat evolved for 1 gram atom of metal.	
					In large Calories (20°).	In kilojoules.
Zn +	$HCl.20H_2O$	7.496	3462	65.37	30.19	126.8
Al +	$HCl.20H_2O$	0.7470	3474	27.1	126.0	527
Mg +	$HCl.200H_2O$	0.8492	3846	24.32	110.15	460.6

[1] Richards, THIS JOURNAL, 25, 209 (1903).

The direct comparison of these numerical values with Thomsen's is not immediately possible, because in all cases the acid used by us was of a different concentration from that used by him. It has already been shown that Thomsen's method of calculating for more dilute acids was erroneous, so that only his actual uncorrected results with acids more concentrated than $HCl.200H_2O$ are worthy of consideration.

An essential part of the research, without which the results recounted in the present paper are incomplete, is therefore the precise determination of the heats of dilution of the several acid solutions concerned. This work has already been almost finished, awaiting only a few final determinations for completion. The details will soon follow in a second paper.

Summary.

1. The new method of adiabatic calorimetry was applied to the solutions of metals in acids. The method is particularly adapted to the determination of the energy change involved in these reactions on account of the length of time required by them.

2. The faults in the old method of estimating the weight of metal dissolved are pointed out and a method of avoiding them is described.

3. It has been shown that in order to insure the complete equality of temperature during the reaction, the stirring within the calorimeter must be very vigorous. All the previous results are probably in error from lack of this knowledge.

4. The quantity of heat generated by stirring a liquid is shown to be increased nearly 10 times when the rate of stirring is doubled.

5. The cooling effect of the evaporation of the acid solution into the escaping hydrogen has been directly evaluated and a suitable correction applied.

6. The quantity of oxide on the surface of the metals employed was shown to be extremely small, and the purity of the materials was carefully investigated, suitable corrections being applied when necessary.

7. The heats of solution of the metals zinc, aluminium, magnesium, cadmium, and iron in hydrochloric acid were determined.

8. The error in Thomsen's method of calculating the heat of solution of a metal in dilute acid from the data obtained with concentrated acid is pointed out.

9. The second part of this paper, containing the essential heats of dilution concerned, will follow soon.

AN ADIABATIC CALORIMETER FOR USE WITH THE CALORIMETRIC BOMB.

BY FRANCIS G. BENEDICT AND HAROLD L. HIGGINS

Received January 24, 1910

The calorimeters generally used with the calorimetric bomb are subject to error due to thermometer lag and exchange of heat with the surrounding media. The thermometer lag is seldom taken into consideration, although Richards[1] shows it is likely to be the cause of a considerable error. The exchange of heat with the surrounding media involves the use of an elaborate, time consuming, cooling correction, which can hardly gauge the loss of heat with any great accuracy. If, however, the calorimeter is rendered adiabatic by keeping the media surrounding it always at the same temperature as the calorimeter itself, both of these errors are avoided.

In 1895, in applying calorimetry to experiments on man, Rosa[2] constructed a large chamber which was made adiabatic by arbitrarily cooling and heating an outer zinc wall to correspond with the fluctuations in temperature of the copper wall of the calorimeter proper. By this method any interchange of heat was avoided and the principle has been found very satisfactory in respiration calorimeters. In connection with the respiration calorimeter at Wesleyan University, considerable work was done with the calorimetric bomb, including the production of a modification of the Berthelot bomb.[3] Experiments were also made there by one of us in an attempt to apply adiabatic conditions to the bomb calorimeter. To this end, special forms of apparatus for heating electrically a surrounding water jacket were employed, but owing to the difficulty in properly insulating the heating wires, the experiments proved unsuccessful. Meanwhile the excellent apparatus of Richards, Henderson and Frevert[4] appeared, an adiabatic calorimeter which is admirably designed for the special purposes for which it has been used in Richards' laboratory and which leaves nothing to be desired in regard to accuracy. For practical purposes, however, it is somewhat cumbersome and involves the use of rather large amounts of strong alkali and acid.

On installing a calorimetric bomb at the Nutrition Laboratory for use in measuring the potential energy of food, feces, and urine, experiments were continued to obtain a practical form of adiabatic calorimeter in which the temperature of an outer water jacket should be controlled by electric heating, and the apparatus here described was devised.

Description of Apparatus.—The calorimeter system, the rise in temperature of which gives the data for computing the number of Calories produced during a combustion, is shown in the figure and consists of the bomb A, the calorimeter can B, and the water it contains, the stirrer, and the immersed portion of the thermometer. In our development of

the calorimeter, we have used for the most part a Kröker bomb, but the calorimeter is applicable to any type of bomb with which we are familiar. The calorimeter can is of nickel-plated brass (24 cm. high and 13 cm. in diameter), being 13 mm. higher than the bomb. The stirrer consists of two flat brass rings, encircling the bomb, perforated by a number of holes, and held together by several small brass rods 10 cm. long. This stirrer is connected with the mechanism for raising and lowering it by two rods, C C, which are made of hard rubber to prevent conduction of heat from the calorimeter. On both of these rods, brass eye-joints are used which allow the stirrer flexibility of motion and prevent it from binding. The calorimeter can rests on three hard rubber guides and knife edges, D, within a second can, about 13 mm. of air space surrounding the calorimeter can on all sides.

To prevent the calorimeter system from exchanging heat with the surrounding media, it is placed inside of a water jacket, E, which is always maintained at the same temperature as the calorimeter. This jacket consists of two nickel-plated brass cans, the smaller one (30.5 cm. high and 15.3 cm. in diameter) so fitting into the larger one (35 cm. high and 19 cm. in diameter) that there is an annular space about 17 mm. wide between the two cans. Two slits are cut in opposite sides of the outer can and two small brass tubes with corresponding slits are soldered to the can so as to provide on the one side, F, for the immersion of a Beckmann thermometer and on the other, G, for a turbine stirrer, H. This annular space, with its two cylindrical enlargements, is filled with about 3500 cc. of water. The water is heated or cooled to correspond with the temperature of the calorimeter water; to heat it, a Simplex electric heating coil (6.8 amp., 750 watts), helical in shape, which is immersed in the water, is used; for cooling, cold water from the city mains is admitted through a small pipe at the bottom of the outer can, the excess of water in the jacket passing out through an overflow. A 2° rise in temperature can be obtained in three minutes by passing the current through the heater for 50 seconds; the cooling is much more rapid.

The calorimeter is protected from exchange of heat at the top by means of a cover, which fits snugly in the top of the water jacket and reaches to 13 mm. from the top of the calorimeter can. This cover consists of two dead-air compartments, J and K, separated by an asbestos plate. The side of the lower dead-air compartment, K, is of metal to allow contact with the outer water jacket and so cause this compartment to take the temperature of the water jacket (and consequently that of the calorimeter) in preference to the temperature of the room air. The other parts of the cover are of non-conductible material—fiber and asbestos—, the top consisting of a larger sheet of fiber for convenience in handling. Soft rubber packing is on the bottom of the cover. Three hard rubber tubes pass through the cover, two for the stirrer rods and one for the thermometer, and the ignition wires pass through a small groove on one side.

Auxiliary Apparatus.—The cans are encased in a wooden box, which serves as a support and also protects them from undue local heating or cooling. A door in front opens to a pet-cock on the water jacket for emptying the latter if desired.

A motor, resting on a shelf back of the box, actuates the two stirrers. The outer stirrer is connected directly to the motor shaft by a cord, and rotates about 750 times a minute. The inner stirrer is raised and lowered 44 times per minute, a distance of 6.5 cm., by means of a worm gear fastened directly to the armature shaft of the motor. This worm gear is connected to the stirrer by a cord passing over pulleys on the back of the box to a cross bar with spring, L, which grips the tops of the stirrer rods.

The ignition of the substance in the bomb is accomplished by a 110-volt current passing through three 32 c. p. lamps in parallel; these lamps are placed in receptacles beneath the shelf upon which the motor rests. The wires are attached to the bomb before lowering it into place in the calorimeter, and later attached to a plug outside which connects it to the switch used for ignition; this avoids handling the wires under water after the bomb is immersed.

The electric switches have been placed on the front of the case. One controls the 110-volt circuit, and there is one each for the motor, the electric heater, and the ignition. Two push buttons for the thermometer tappers are also placed on the front of the case.

The thermometers are held by a special form of support, M, consisting of two brass tubes, one for each thermometer. Attached to the top of each thermometer is a collar with a handle, which fits into a slit in the wall of the tube support. When lowered, the collar handle rests on the bottom of the slit; when raised, the handle is turned 90° and thus rests in a notch in the top of the support. When the thermometers are not being used, the whole support is swung to one side out of the way; when they are to be used, the support is swung back into position and automatically centers itself so that both thermometers are directly above the corresponding openings in the cover. We have been using two Beckmann thermometers, readable to 0.001°, although a cheaper thermometer could doubtless be used for the water jacket. For tapping the thermometer, we use the hammer of a small electric bell, N, attached to the thermometer support.

Method of Making a Combustion.—In a combustion, the substance to be burned is prepared, weighed, and put in the bomb and the bomb charged to 25 atmospheres with oxygen. The calorimeter water is brought to a temperature of about 2° lower than that of the room, as it is generally planned to have a 2° rise in the combustion and it has been found advantageous to have the final temperature of the calorimeter about the same as the room temperature. The calorimeter water is then weighed. The system is assembled; the calorimeter can, with water and stirrer, is lowered into the jacket, and then the bomb, connected with the ignition wires, is in turn lowered into the calorimeter can; the cover is put in place, the thermometers adjusted, and the stirrers connected and started. By means of the electric heating coil and the cold water, the temperature of the water jacket is adjusted to about 0.1° lower than that of the calorimeter system and a temperature constant to within 0.001° is readily obtained in the calorimeter system for several minutes. It has been found that the water jacket should be slightly colder than the water in the calorimeter to compensate for the small amount of heat entering from the warmer room, probably through the tubes in the cover.

After the temperature of the calorimeter water has remained constant for several minutes, showing no interchange of heat, the switch for heating the water jacket is closed. The current is then passed through the heater for such a length of time as will be necessary to raise the outer water to the temperature it is expected the inner water will reach after the substance in the bomb is burned. The length of time required for this is calculated from the known fact that the heater gives a 1° rise for every 25 seconds the current is on. Forty-five seconds after the current is turned on, another reading of the calorimeter thermometer is taken, and the substance is ignited. The heating of the water jacket is begun before ignition, as the electric heater is somewhat sluggish. During the 45 seconds the current is on before ignition, the rise in temperature of the outer water indicates on the thermometer about 0.2°, showing that there is very little, if any, interchange of heat, but the rise of temperature becomes considerably more rapid after one minute, and the temperatures of the calorimeter and the water jacket are found to rise at about the same rate. After the ignition, the two thermometers are watched very carefully and if the temperature of the water jacket does not follow very closely the temperature of the calorimeter water, it is heated by the electric heater or cooled by cold water, as may be necessary to keep the two temperatures the same. Generally, however, little or no adjustment of the temperature of the outer water is necessary, as a careful timing of the heating of the jacket at the start will regulate the temperature. Readings of the thermometers are recorded every minute, and three or four minutes after ignition, the thermometer in the calorimeter water is found to attain a maximum reading which will remain constant practically as long as desired. The combustion now being completed, the thermometers are removed, the bomb opened and rinsed with water, and the rinsings titrated for nitric acid, using methyl orange as an indicator.

Calculation of Results.—The initial constant reading of the temperature of the calorimeter system subtracted from the final constant reading after the burning of the substance gives, after applying thermometer corrections, the total rise in temperature of the system. This rise multiplied by the weight of water (plus the hydrothermal equivalent of the apparatus) gives the total number of Calories liberated. From this is subtracted the heat resulting from the ignition (electrical energy and combustion of kindling material, such as cotton thread or iron wire) and from the formation of nitric acid. The result, divided by the weight of the substance, gives the number of Calories per gram of substance.

The water equivalent of the calorimeter system was determined by us by burning known amounts of cane sugar (rock candy), the heat of combustion of sugar being taken as 3957 Calories per gram.[1] The amount of water used in our calorimeter has, for convenience in calculating, been such that the weight of water plus the hydrothermal equivalent is equivalent to 2500 grams of water.

2.057° × 2500 g. = 5143 cal.
5143 — 35 = 5108 cal.
5108 ÷ 1.2905 = 3958 cal. per gram.

---

[1] This value is that found by Fischer and Wrede, *Sitzungsberichte d. Koniglich. Preuss. Akad. d. Wissenschaften*, 5, 129 (January, 1908). If later investigation gives another more accurate result, the results obtained assuming 3957 as correct may be revised by proportion.

The apparatus here described has proved very efficient, and we are able to obtain very satisfactory duplicate results in two combustions of the same substance. Practically no trouble is experienced in obtaining a constant temperature of the calorimeter system either at the beginning or end of a combustion; in fact, with the room temperature even 5° higher than that of the calorimeter water, constant readings have been obtained. With this calorimeter, the time required for a combustion is much less than usual, inasmuch as long preliminary and final periods are avoided and the calculation is materially simplified.

A SIMPLE SYSTEM OF THERMODYNAMIC CHEMISTRY BASED UPON A MODIFICATION OF THE METHOD OF CARNOT.

BY EDWARD W. WASHBURN.

Received January 19, 1910

CONTENTS.

1. Introduction. 2. Description of the perfect thermodynamic engine. 3. The vapor pressure of a pure substance 4. The homogeneous physical mixture. 5. Homogeneous chemical equilibrium. 6. Heterogeneous chemical equilibrium. 7. Electromotive force 8. The colligative properties of a solution. 9. Summary and conclusion.

1. Introduction.

In order to determine the maximum amount of work which can be obtained from a given amount of heat by a fall in temperature, Carnot, in 1824, performed an "imaginary experiment," the Carnot Cycle. In performing this "experiment" Carnot made use of the simplest and most familiar example of a mechanism for obtaining work from heat, the cylinder and piston of the steam engine. He realized clearly that in order to obtain the desired relation he had only to *imagine* a mechanism which could operate under the most ideal conditions, one which represented the limit approached by all actual machines of the same class, as the losses due to friction, heat radiation and conduction, incomplete external compensation, etc., became indefinitely small. The reversible cyclical process thus invented by Carnot and later slightly modified by the work of Clapeyron and of Clausius, constitutes to-day the basis for the derivation of the mathematical formulation of the Second Law of Thermodynamics. Resting upon this law, the whole structure of thermodynamics has since been built up.

In the process of constructing our systems of thermodynamic chemistry, two general methods may be distinguished. The first of these, the analytic method, starts with Clausius' formulation of the Second Law in terms of entropy. The manner in which the entropy function might be used with advantage by the chemist was first illustrated by Horstmann, who applied it to many problems in chemical equilibrium. The later advocates of the analytic method, however, have not found it convenient to restrict themselves to the entropy function, but have defined and made use of a number of other thermodynamic functions. Willard Gibbs, in his masterly contributions to thermodynamic chemistry, defined four of these functions, his ε, ψ, χ and ζ functions; the ζ function, or the so-called Gibbs thermodynamic potential, being the one most commonly employed to-day. The system invented by Gibbs has been followed by Duhem, Planck, van der Waals, van Laar, and others, usually however receiving some modification at the hands of each investigator. Thus Planck, instead of using Gibbs' Zeta function, prefers another potential which he defines as equal to $-\zeta/T$, where T is the absolute temperature; and recently G. N. Lewis has constructed a very simple analytic system of thermodynamic chemistry by introducing two new functions, the fugacity, Ψ, and the activity, ξ, which are connected with each other by the equation, $\Psi = \xi RT$, and whose relation to Gibbs' Zeta function is expressed by the equation $\zeta = RT \ln \Psi + f(T)$. Although here classed among the analytic methods, this system owes a large part of its increased simplicity to the fact that its fundamental equations are derived by employing the second general method instead of starting with the entropy function as might have been done.

The second general method of constructing a system of thermodynamic chemistry is the Carnot method, or, as it is usually called to-day, the cyclical process method. This has been the favorite method among chemists, and to it we owe most of our advances in this branch of chemistry, as illustrated by the work of such men as van't Hoff, Ostwald, Arrhenius and Nernst. It is the simplicity of the processes involved in this method and the consequent protection against error which constitute its great advantages over the more intricate and abstruse, but yet not necessarily more rigorous methods based upon the entropy and thermodynamic potential functions. This has been well stated by Mach in his comment upon the discoverer of the second law: "Carnot, by whose ideas the whole of thermodynamics is ruled to-day, ... affords us the most pleasing picture of a genius who, without apparent exertion and without the labored application of intricate and cumbersome scientific methods, but solely through the consideration of the simplest processes, is able, almost without effort, to perceive the most fundamental truths."

The cyclical process method of deriving thermodynamic equations as applied by many of its advocates has been the subject of considerable adverse criticism mainly upon two grounds: (1) As usually carried out, the cyclical process consists of a series of steps, usually four, in each of which certain amounts of work and of heat are involved, the desired result being obtained by combining properly all the work and heat terms of the various steps in the cycle. The complete process is consequently rather long in some instances and is regarded by some writers as very cumbersome compared with some of the corresponding analytic methods. (2) In writing down the work and heat terms for the various steps of the cycle, it is customary to introduce some assumption such as the perfect gas law or one of the laws of dilute solutions, with the result that a rigorous, purely thermodynamic equation is not obtained, but only an approximate one containing one or more arbitrary assumptions. The possibility of introducing these assumptions is the most serious objection which can be offered to the cyclical process method, as carried out at present. So general is this practice, that in the text-books employing this method one looks almost in vain for exact thermodynamic equations such as those relating to chemical equilibrium, for example.

In the following pages a modification of the Carnot method will be described which eliminates completely both of these objections: (1) the cycle is reduced to a single step and the desired relation can be written down simply by inspection; (2) the differential equation so obtained will always be entirely rigorous because it is impossible to introduce into the process any assumptions except the Second Law of Thermodynamics. This gain in simplicity and exactness is accomplished by joining together the various pistons of the ordinary cycle so as to form a single complete engine which we shall call the Perfect Thermodynamic Engine. After describing the construction and operation of this engine, its application will be illustrated by using it in order to derive a number of the more important relations of thermodynamic chemistry. While the treatment of the subject in the following pages must necessarily be rather concise, it can, I believe, be followed easily by any chemist familiar with the elements of thermodynamics and the calculus.

2. The Perfect Thermodynamic Engine.

Figures 1, 2 and 3 illustrate different types of the engine, the essential parts of which are the following (see Fig. 1):

Two *reaction chambers* (**E** and **E′**) contain the system under consideration. Each chamber is placed in a *reservoir* (**R** and **R′**) of infinite heat capacity for the purpose of maintaining a constant temperature within the chamber. Each chamber is fitted with a set of *cylinders* (**A, B, D, A,′ B′, D′**, etc.) which connect with it through suitable *semipermeable membranes*, **aa, a′a′**. The cylinders are fitted with frictionless pistons (**A, B, D, A′, B′, D′**, etc.), some of which are semipermeable, others impermeable. Each corresponding pair of pistons is connected by a rigid piston rod, thus forming a *compound piston* (**AA′, BB′, DD′**, etc.). The piston rods have zero heat capacities and are non-conductors of heat and electricity, and the two reservoirs, **R** and **R′**, are otherwise insulated from each other so that no irreversible transfer of heat can take place between them. During the *operation* of the engine the following conditions must be fulfilled: (1) The two reservoirs must never differ from each other, in temperature, by more than an infinitesimal amount; when such a difference exists, the temperature of **R** will be designated by T and that of **R′** by $T + dT$; (2) The pressure difference against the two heads of a compound piston must never exceed an infinitesimal amount; the pressures exerted against the pistons of **E** will be designated by p, P, etc., those exerted against the pistons of **E′**, by $p + dp$, $P + dP$, etc. The *operation* of the engine consists in the movement of the com-

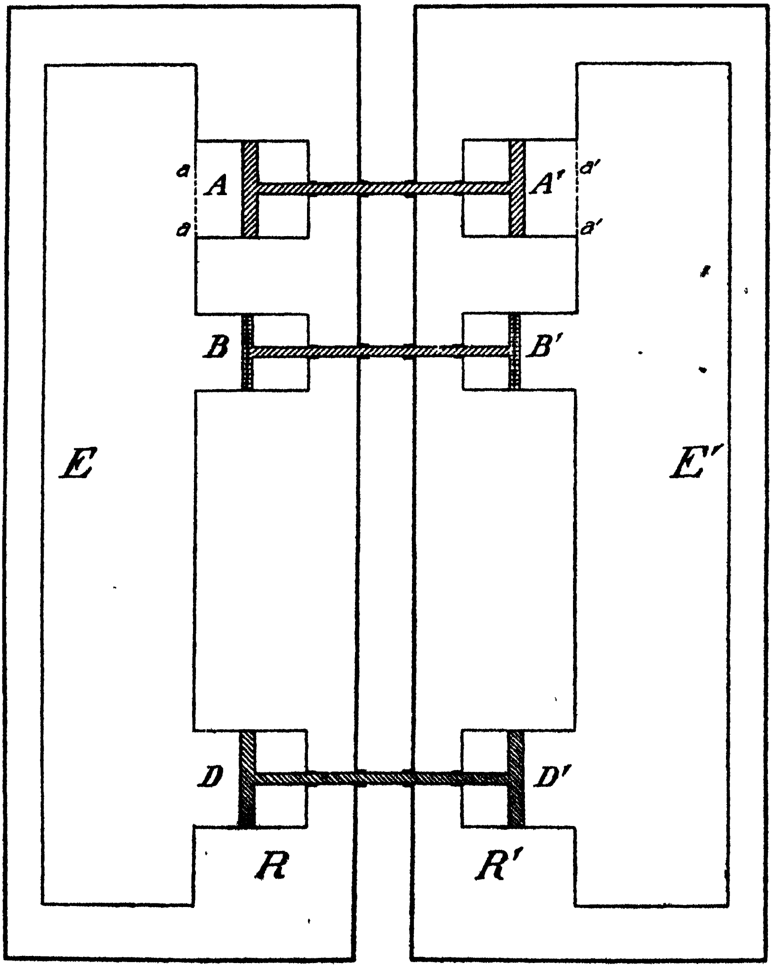

Fig. 1.

pound pistons through finite distances, accompanied by corresponding processes which take place within the reaction chambers. Other conditions which must be fulfilled during this operation are (3) that each compound piston must always move so as to produce the maximum amount of external work, there being applied to it a compensating external pressure substantially equal to the pressure difference on the two piston-heads; and (4) that the rates of motion of all the pistons must be so regulated that the equilibrium within the reaction chambers remains undisturbed. In other words, the engine must operate reversibly.

By the Second Law of Thermodynamics, the following two theorems, regarding the work produced during the *operation* of the engine, are true:

Theorem I.—The total work produced during the isothermal *operation* (temperature of **R** = temperature of **R**′) of the engine is equal to zero.

Theorem II.—When the engine operates as a heat engine (temperature of **R** = T, that of **R**′ = $T + dT$), the total work produced is equal to $Q\ dT/T$, where Q is the heat absorbed from reservoir **R**′.

It should also be noted that the algebraic expression for the work produced by any compound piston during the operation of the engine will have a positive sign when the motion is from right to left and a negative sign when the motion is from left to right. Since one complete "operation" of the engine, as we shall use the term, is not a complete cycle, it will be necessary to demonstrate the truth of these two theorems. This will be done in the next section, in which certain other details concerning the construction and operation of the engine will also be described.

3. The Vapor Pressure of a Pure Substance.

The equilibrium between vapor and liquid (or vapor and solid) in a one-component system may be altered: (1) by changing the total pressure on the liquid (or solid) phase at constant temperature; (2) by changing the temperature of the system while keeping the pressure on the liquid (or solid) phase constant; or (3) by changing the temperature of the system and at the same time allowing the total pressure on the liquid (or solid) phase to vary in such a manner that it is always equal to the vapor pressure. We shall make use of the perfect thermodynamic engine in order to determine the separate effects of these different factors upon the vapor pressure of a pure liquid. The treatment for the case of a pure solid is perfectly analogous.

The Pressure Coefficient (T = *const.*).—We shall use the engine shown in Fig. 1, omitting, however, pistons and cylinders **BB**′. The arrangement of the engine is as follows:

Chamber E: Filled with the liquid whose vapor-pressure, acting through the membrane **aa** (permeable to vapor only) against piston **A**, is p. Total pressure on liquid, acting against piston **D**, is P. Temperature of **R** = T.

Chamber **E′**: Exactly as **E** except that the total pressure on the liquid, acting against piston **D′**, is $P + dP$ and the vapor-pressure, acting against piston **A′**, is $p + dp$.

To operate the engine allow piston **AA′** to move reversibly toward the left until one mol of the vapor in cylinder **A** condenses through the membrane into chamber **E** and an equal volume v is evaporated from chamber **E′** into cylinder **A′**. At the same time and at such a rate as not to disturb the equilibrium in either chamber, piston **DD′** moves reversibly toward the right through the volume V occupied by one mol of the liquid under the pressure P. The work done by piston **AA′** is vdp, and that done by piston **DD′** is $-VdP$. By the Second Law (*i. e.*, Theorem I) the total work is equal to zero, which gives us the equation

$$vdp - VdP = 0 \qquad (1)$$

or

$$(\partial p/\partial P)_T = V/v, \qquad (2)$$

an equation first obtained by Poynting.[1]

If the vapor obeys the perfect gas laws, equation (2) assumes the form

$$(\partial \ln p/\partial P)_T = V_0(1-\alpha P)/RT \qquad (3)$$

where V_0 is the molecular volume of the liquid under zero pressure and α is the mean coefficient of compressibility of the liquid as defined by the equation, $\alpha = (V_0 - V)/V_0P$. The equation can now be integrated. Since the right-hand member of equation (2) is necessarily positive, the vapor pressure always increases with increase in pressure on the liquid phase. The coefficient, $(\partial p/\partial P)_T$, is small for temperatures considerably removed from the critical temperature (thus for water at 0°, $(\partial p/\partial P)_{T=273°} = 3.6 \cdot 10^{-6}$ mm. per atmosphere) but increases with the temperature and becomes equal to 1 at the critical temperature.

Proof of Theorem I.—We have assumed Theorem I in writing equation (1). In order to demonstrate the truth of this theorem for the present case, it is only necessary to show that the engine can be restored to its original condition without leaving any residual effect in the surroundings. Turning, therefore, to our engine after the completion of the operation, we notice that as regards the vapor, the final state of the system differs from its original state in that we have (in cylinder **A′**) $1 + dx$ mols of vapor occupying the volume v under the pressure $p + dp$ instead of having (in cylinder **A**) 1 mol of vapor occupying the volume v under the pressure p. This means that while only one mol of liquid has been produced in chamber **E**, $1 + dx$ mols of liquid have been evaporated from chamber **E′**, dx being obviously expressed by the relation $dx = (\partial x/\partial p)_{v,T}dp$. But the removal of this dx mol of liquid from chamber **E′** would, unless compensated in some manner, cause a corresponding change in the total pressure in this chamber, because it will be remembered that during the operation of the engine, piston head **D**$'$ moves toward the right simply through the volume V of one mol of liquid under pressure P, not through the volume of $1 + dx$ mols of liquid under the pressure $P + dP$. To avoid this pressure change a little device, **X** (not shown in Fig. 1, but shown in Fig. 1*a*), acts automatically during the operation of the engine to maintain a constant pressure in chamber **E**$'$. This device applies the constant pressure $P + dP$ to a little auxiliary piston, π', which, during the operation of the engine, gradually introduces reversibly into chamber **E**$'$, such an amount, dx' mol, of liquid as suffices to maintain the constant pressure $P + dP$ within this chamber. During this process (which we need not consider as a part of the "operation" of the engine for reasons stated below) the device **X** gives out the energy $(P + dP)dV'$.

---

[1] Poynting, *Phil. Mag.* [5], 12, 32 (1881).

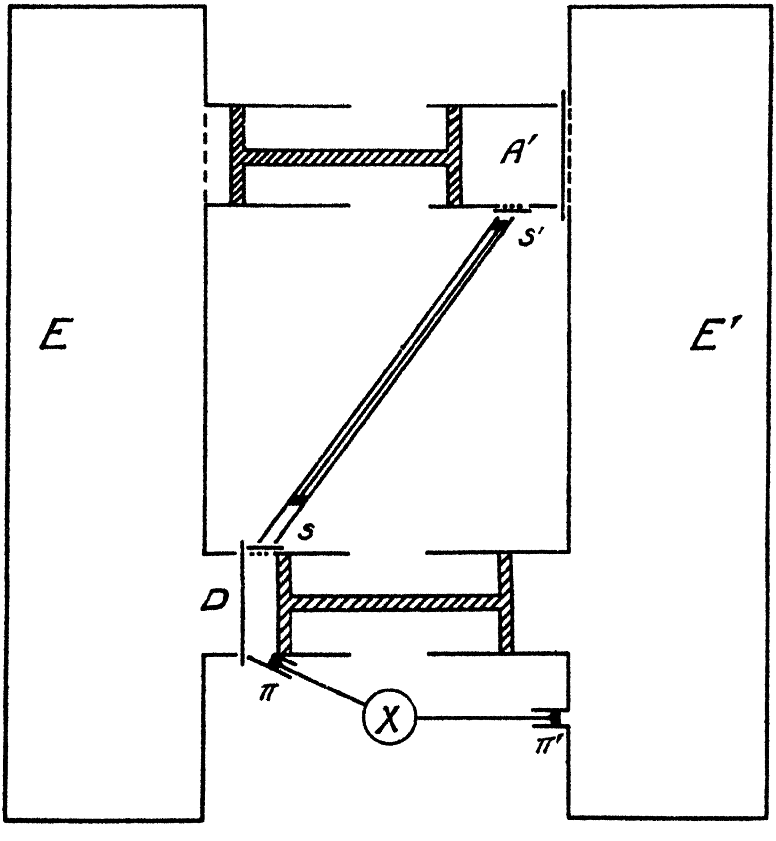

Fig. 1*a*.

As soon as the "operation" of the engine has been completed, another automatic device (shown in Fig. 1*a*) immediately acts to restore the system to its original condition. This device is the little compound piston **ss′**. The head **s′** rests against a slider which separates it from cylinder **A′** and which at the conclusion of the "operation" of the engine slides back so that the vapor pressure $p \pm dp$ acts against the piston head **s′**. Below the piston head **s** is contained dx mol of vapor at the pressure p separated from cylinder **D** by a semipermeable membrane and by an impermeable slider which on sliding back puts the dx mol of vapor into communication with the liquid in cylinder **D**, with which it is in equilibrium. The action of this device is as follows· When the "operation" of the engine has been completed the one mol of liquid in cylinder **D** and the $1 + dx$ mols of vapor in cylinder **A′** are automatically cut off from the rest of the engine (as shown in Fig. 1*a*), the little sliders at **s** and **s′** move back and piston **ss′** moves downward drawing dx mol of vapor out of cylinder **A′** (the pressure consequently dropping to p) and condensing it as liquid into the one mol of liquid in cylinder **D**, whose pressure thereby is raised to $P + dP$. *At the same time*[2] the little piston, π, which is attached to the device **X** moves downward through the volume dV'. The system is now in its original condition, *i. e.*, we have 1 mol of vapor under the pressure p and $1 + dx'$ mols of liquid under the pressure $P + dP$, which was the condition of the system before the operation of the engine.

Let us consider the work produced by the action of these various automatic devices which serve to restore the system to its original condition. The piston **ss′** moves through the volume dv under the pressure dp and therefore performs the work $dp\,dv$, which is a differential of the second order and consequently negligible. During the movement of the little piston π the device **X** takes up the energy $(P + dP)dV'$. But this is the same amount of energy which it gave out previously to piston π'. The operation of the device **X**, therefore, involves no work. The total work involved in restoring the system to its original condition, after an "operation" of the engine, is therefore made up of differentials of a higher order than the first and is consequently entirely negligible in comparison with the work performed during the "operation" itself. Although we have shown this to be true only for the simple case just considered, it is clear that it must also be true for any engine of this type, in which the intensity factor of some form of energy is different in the two chambers because of a difference dP in the total pressures on the chambers, and whose operation consists in removing one or more substances from one chamber and forcing them into the other by means of compound pistons moving in a manner analogous to the simple case just considered. *Theorem* I *is therefore true.*

---

[2] Strictly speaking, the movement of piston π should not begin until such a portion of the dx mol has been forced into D, as suffices to raise its pressure to $P + dP$.

The Temperature Coefficient (*P = const.*).—Let us now consider the effect of temperature changes upon the vapor pressure of a liquid which is under constant external pressure P, such changes as would occur for example on heating the liquid in an open vessel exposed to the atmospheric pressure. As in the previous case, we will make use of the engine shown in Fig. 1, omitting cylinder **BB′** The arrangement is as folllows:

Chamber **E**: Filled with the liquid whose vapor pressure acting through the semipermeable (*i. e.*, only to the vapor) membrane against piston **A** is p. Total pressure on liquid, acting against piston **D**, is P. Temperature of **R** $= T$.

Chamber **E′**: Exactly as **E** except that the temperature of **R′** is $T + dT$ and the vapor pressure, acting against piston **A′**, is $p + dp$.

The operation of the engine is the same as in the preceding case. Piston **AA′** moves reversibly toward the left under the pressure dp, until 1 mol of the vapor in cylinder **A** is condensed into **E** and an equal volume evaporated from **E′** into cylinder **A′**. Piston **DD′** moves toward the right, under zero pressure, through the volume V occupied by one mol of the liquid, in **E**. The work done by piston **AA′** is vdp, that done by piston **DD′** is zero. We have, therefore, by the Second Law (*i. e.*, *Theorem* II),

$$vdp = L_p dT/T \tag{4}$$

or

$$(\partial p/\partial T)_P = L_p/vT, \tag{5}$$

an equation previously obtained by Lewis[3]

L_p, the heat absorbed from reservoir **R′**, is the molecular heat of vaporization of the liquid under constant pressure. Since this is a positive quantity, the vapor pressure always increases with rise in temperature. If the vapor behaves as a perfect gas, we can put $v = RT/p$ in equation (5), which gives us

$$(\partial \ln p/\partial T)_P = L_p/RT^2. \tag{6}$$

To integrate, it is only necessary to express L_p as a function of T, which can be readily done by means of the thermodynamic relation,

$$\partial L_p/\partial T = c_p - C_p, \tag{7}$$

where c_p and C_p are the molecular heat capacities of vapor and liquid respectively, under constant pressure.[4]

Proof of Theorem II.—Let us now return to our engine and compare its final state with its initial state. As regards the vapor we have (in

---

[3] *Proc. Amer. Acad.*, 37, 53 (1901); *Z. physik. Chem.*, 38, 205 (1901).

[4] Equation 7 also contains the assumption that the vapor behaves as a perfect gas. The purely thermodynamic equation for the temperature coefficient of L_p is

$$(\partial L_p/\partial T)_P = c_p - C_p + L_p/T - (L_p/v)(\partial v/\partial T)_p. \tag{7a}$$

cylinder **A′**) 1 + dx mols of vapor occupying the volume v at the temperature $T + dT$ and pressure $p + dp$ instead of having (in cylinder **A**) 1 mol of vapor at the temperature T and pressure p. dx is defined by the equation $dx = (\partial x/\partial p)_{v,T}(\partial p/\partial T)_p dT + (\partial x/\partial T)_{v,p} dT$, and may, in general, be either positive or negative since the second term of this expression is essentially negative. 1 + dx mols of liquid have consequently evaporated from chamber **E′** during the operation and in order to prevent a consequent change in pressure in this chamber, the automatic device **X** acts just as in the preceding case to introduce dx mol of liquid into **E′**, replacing that which evaporates into cylinder **A′**, and thereby performs the work PdV.

At the completion of the operation of the engine, the 1 + dx mols of vapor are cut off from cylinder **A′** and brought into reservoir **R**, whereupon the temperature returns to T. By means of the piston **ss′** (Fig. 1*a*) dx mol is then removed from it (its pressure thereupon falling to p) and condensed into the 1 mol of liquid which has been cut off from chamber **E** and whose pressure is thereby raised to $P + dP$. The work involved in this operation is that done by piston **ss′**, which is $dp\,dv$. The one mol of liquid is now brought into reservoir **R′** (whereupon its temperature returns to $T + dT$) and is connected to the device **X**, which removes dx mol from it, its pressure thereby falling to P. The whole system is now in its original condition. The work absorbed by the device **X** in this last step is $P\,dV$, the same amount which it previously gave out. Therefore the restoration of the system to its original condition after the operation of the engine does not leave any residual effects in the surroundings as far as work is concerned. As regards the heat absorbed from reservoir **R′** during the restoration, it is clear that since the temperature change is infinitesimal, the heat absorbed must be a differential quantity and consequently negligible in comparison with the finite amount of heat L_p absorbed during the operation of the engine. *Theorem* II *is therefore true.*

These two examples suffice to show that the restoration of the system to its original condition after the operation of the engine involves no work or heat terms which need to be considered. The whole effective work of the process is therefore performed entirely by the compound pistons of the engine and we may therefore, in the future, confine our consideration solely to these pistons and apply Theorems I and II directly to them. The various automatic devices which have been described for restoring the system to its original condition are understood to be a part of every engine, but since their action does not involve any work it will not be necessary to pay any attention to them in the future.

The Temperature Coefficient ($P = p$).—The latent heat of vaporization of a liquid is usually determined by condensing (in a calorimeter) the vapor of the boiling liquid. Under these conditions the liquid always vaporizes, not under constant pressure at all temperatures, but under its own vapor pressure at each temperature. The temperature coefficient of the vapor pressure under these conditions can be at once written down, by using the engine shown in Fig. 1. The arrangement is exactly as in the preceding case except that the pressure against piston **D** is p and that against piston **D′** is $p + dp$. The operation is the same as before and we obtain at once the relation

$$vdp - Vdp = L_p dT/T \tag{8}$$

or

$$(\partial p/\partial T)_{P=p} = L_p/(v-V)T \tag{9}$$

which is the familiar Clausius-Clapeyron equation.

L_P and L_p, the latent heats of vaporization of a liquid under the pressure P, and under its own vapor pressure, p, respectively, will not differ much unless the difference between P and p is large or the difference between v and V is small. In the case of water, for example, if $P = 1$ atmosphere, the difference between L_P and L_p could never exceed 0.005 per cent. L_p is the one which is usually determined experimentally, but A. W. Smith[1] has recently made a very accurate determination of L_P by bubbling air through water, the temperature of which was kept constant by electrical heating.

Solid-liquid Equilibrium. By filling the chambers of the engine with a pure solid and the cylinders with the pure liquid in equilibrium with it, we can study the effects of temperature and pressure upon such a system, in exactly the same way as for the liquid-gas or solid gas equilibrium described above, the equations obtained being identical in form with those just derived

4. The Homogeneous Physical Mixture.

In this section we shall make use of the perfect thermodynamic engine in deriving the equations expressing the effects of pressure, composition and temperature upon the partial vapor pressures and the osmotic pressures for any homogeneous physical mixture. Before taking up the derivations, however, it will be necessary to define accurately the term "osmotic pressure" as we shall use it.

Consider any homogeneous liquid mixture of n components (A, B, C, etc.) under the external pressure P. Let us take any one of the components, A for example, in the pure liquid state and subject it to such an external pressure P_A that its vapor pressure shall be equal to its partial vapor pressure from the mixture. If now the pure liquid A be placed in communication with the mixture through a membrane permeable only to A, the system will be in equilibrium as respects the passage of A into or out of the mixture. The difference between the pressures P_A and P is called the "osmotic pressure." For the simplest type of mixture it depends only upon the specific volume and compressibility of the pure substance A and upon its mol fraction in the mixture, for a given value of T and P. It would seem preferable therefore to speak of this pressure difference as the "osmotic pressure" of the substance A, since it is essentially determined by the properties of this substance. Principally on account of historical reasons, however, it is customary to speak of this pressure difference as the "osmotic pressures" of all the other components of the mixture except the substance A. In what follows it is essential that this pressure difference shall be referred directly to the substance which is present in the pure liquid state, and we will therefore speak of it as "the osmotic pressure referred to A as the solvent" or, briefly, as "the osmotic pressure referred to A." *In any homogeneous (gaseous, liquid or solid) mixture, therefore, the osmotic pressure* Π_A *referred to any constituent,* A, *is defined by the equation,* $\Pi_A = P - P_A$, *where* P *is the external pressure on the mixture and* P_A *is the external pressure on the pure substance* A *(in the same state of aggregation) when it is in equilibrium with the mixture through a membrane permeable only to itself.*[6]

---

[1] *Phys. Rev.*, 25, 145 (1907).

The following treatment, together with the equations obtained, is equally applicable to a solid, liquid or gaseous homogeneous, physical mixture of any number of components, but in developing our equations we shall find it convenient to fix our attention upon a homogeneous liquid mixture of say four components. The composition of the mixture is expressed by the equation $N_A + N_B + N_M + N_N = 1$, where N_X represents the mol fraction of any constituent X. The mol fraction of any constituent (A, for example) is defined by the equation $N_A = n_A/(n_A + n_B + n_M + n_N)$, where n_A, n_B, etc., represent the number of mols of the various constituents in any given quantity of the mixture.

The Pressure Coefficient (N, T = *const.*).—1. Vapor Pressures: Using the engine shown in Fig. 2, the arrangement is as follows (Temperature of **R** = temperature of **R′** = T):

Chamber **E**: Filled with the liquid mixture under the total pressure P applied by means of piston **D**. The partial vapor pressures of the various constituents (each acting through a membrane permeable only to its own vapor), are, p_A acting against piston **A**, p_B against **B**, p_M against **M**, and p_N against **N**.

Chamber **E′**: Filled with the liquid mixture under the total pressure $P + dP$ applied by piston **D′**, the partial vapor pressures being $p_A + dp_A$ acting against piston **A′**, $p_B + dp_B$ against **B′**, $p_M + dp_M$ against **M′** and $p_N + dp_N$ against **N′**.

[6] This definition is essentially the same as that given by A. A. Noyes (*Z. physik. Chem.*, 35, 707 (1900)). Its advantages over the more common one will become evident as we proceed.

At the beginning of the operation each of the four vapor pistons is at the right-hand end of its stroke, so that piston heads **A′**, **B′**, **M′**, and **N′** are in contact with the semipermeable membranes separating the cylinders from **E′**. The operation of the engine consists in the simultaneous movement of all four vapor pistons toward the left until 1 mol of the mixture has been evaporated from **E′** and condensed into **E**. At the same time piston **DD′** moves toward the right through the volume $(\Sigma\overline{V})$ of one mol of the liquid mixture. By the Second Law (Theorem I) the total work is equal to zero, giving us the equation,

$$N_A v_A dp_A + N_B v_B dp_B + N_M v_M dp_M + N_N v_N dp_N - (\Sigma\overline{V})dP = 0 \quad (10)$$

or

$$(N_A v_A \partial p_A + N_B v_B \partial p_B + N_M v_M \partial p_M + N_N v_N \partial p_N/\partial P)_{N,T} = (\Sigma\overline{V}) \quad (11)$$

which for brevity we shall write in the form

$$[(\Sigma N_A v_A \partial p_A)/\partial P]_{N,T} = (\Sigma\overline{V}) \quad (12)$$

In these equations V_x is the volume of one mol of the substance X in the vapor state under the pressure p_x.

2. Osmotic Pressures: If the cylinders contain the pure components in the liquid state instead of the gaseous state the respective partial pressures are osmotic pressures instead of vapor pressures, and allowing the engine to operate as before, we can write down at once the equation

$$[(\Sigma N_A V_A \partial \Pi_A)/\partial P]_{N,T} = (\Sigma N\overline{V}) \quad (13)$$

in which V_A, V_B, etc., represent the molecular volumes of the pure substances A, B, etc., in the liquid state under the pressures $P - \Pi_A$, $P - \Pi_B$, etc., respectively.[7]

The Composition Coefficient (P, T = const.).—1. Vapor Pressures: We shall now proceed to determine the effect of a slight change in the composition of a mixture, upon the partial vapor pressures of its constituents. Let us change the mol fraction of constituent A, for example, from N_A to $N_A + dN_A$. The arrangement of the engine is exactly as in the preceding except that the total pressure acting against **D** and **D′** is P for both chambers, the dp differences in the partial vapor pressures being due to the fact that the composition of the mixture in chamber **E′** has been altered by the addition of dN_A mols. of A. The operation of the engine is exactly as above and we have by the Second Law (Theorem I),

---

[7] The expression $(\Sigma N\overline{V})$ is used to represent the volume of one mol of the mixture because this volume may be regarded as equal to the sum of the partial volumes of the components as expressed by the equation $N_A\overline{V}_A + N_B\overline{V}_B + N_M\overline{V}_M + N_N\overline{V}_N = \Sigma N\overline{V}$, in which $\overline{V}_A$, $\overline{V}_B$, etc., represent the *partial* molecular volumes of the respective constituents in the mixture. The partial molecular volume of any constituent is equal to the increase in the volume of an infinite amount of the mixture when one mol of the constituent is added to it. Similar relations may be stated for the quantities $(\Sigma N\overline{L})$ and $(\Sigma N\overline{D})$ which appear in equations (18) and (19).

$$N_{\mathrm{A}}v_{\mathrm{A}}dp_{\mathrm{A}} + N_{\mathrm{B}}v_{\mathrm{B}}dp_{\mathrm{B}} + N_{\mathrm{M}}v_{\mathrm{M}}dp_{\mathrm{M}} + N_{\mathrm{N}}v_{\mathrm{N}}dp_{\mathrm{N}} = 0, \tag{14}$$

or

$$[(\Sigma N_{\mathrm{A}}v_{\mathrm{A}}\partial p_{\mathrm{A}})/\partial N_{\mathrm{A}}]_{P,T} = 0. \tag{15}$$

2. Osmotic Pressures: As in the preceding case, if the cylinders contain the pure liquid components the operation of the engine gives us the equation

$$-[(\Sigma N_{\mathrm{A}}V_{\mathrm{A}}\partial \Pi_{\mathrm{A}})/\partial N_{\mathrm{A}}]_{P,T} = 0. \tag{16}$$

The Temperature Coefficient (*P*, *N* = *const.*).—1. Vapor Pressures: The arrangement and operation of the engine is exactly the same as in the preceding case except that the composition is identical in both chambers and the temperature of **R** = T and that of **R′** = $T + dT$. The Second Law (Theorem II) gives us at once the relation

$$N_{\mathrm{A}}v_{\mathrm{A}}dp_{\mathrm{A}} + N_{\mathrm{B}}v_{\mathrm{B}}dp_{\mathrm{B}} + N_{\mathrm{M}}v_{\mathrm{M}}dp_{\mathrm{M}} + N_{\mathrm{N}}v_{\mathrm{N}}dp_{\mathrm{N}} = (\Sigma NL)dT/T \tag{17}$$

or

$$[(\Sigma N_{\mathrm{A}}v_{\mathrm{A}}\partial p_{\mathrm{A}})/\partial T]_{P,N} = (\Sigma NL)/T \tag{18}$$

where (ΣNL) is the latent heat of vaporization of one mol of the mixture at constant pressure and composition.[7]

2. Osmotic Pressures: With the pure liquids in the cylinders we obtain the equation

$$-[(\Sigma N_{\mathrm{A}}V_{\mathrm{A}}\partial \Pi_{\mathrm{A}})/\partial T]_{P,N} = (\Sigma N\bar{D})/T \tag{19}$$

where $(\Sigma N\bar{D})$ is the latent heat of separation of one mol of the mixture into its pure liquid components under equilibrium conditions. Its exact meaning is clearly evident from the operation of the engine.[7]

Discussion.—The equations which we have just derived involve nothing but the two laws of thermodynamics and they contain all th [illegible] formation which thermodynamics alone is capable of yielding r [illegible] the relations existing among the partial vapor pressures or osm [illegible] sures for a homogeneous mixture. We shall not, in the pres [illegible] discuss these important equations further, although many in [illegible] examples of their transformations and applications in special cases present themselves. It will be sufficient to note here that if the vapors behave as perfect gases, the vapor pressure equations assume the forms

$$[(\Sigma N_{\mathrm{A}}\partial \ln p_{\mathrm{A}})/\partial P]_{N,T} = (\Sigma NV)/RT, \tag{20}$$

$$[(\Sigma N_{\mathrm{A}}\partial \ln p_{\mathrm{A}})/\partial N_{x}]_{P,T} = 0, \tag{21}$$

and

$$[(\Sigma N_{\mathrm{A}}\partial \ln p_{\mathrm{A}})/\partial T]_{N,P} = (\Sigma N\bar{L})/RT^{2}. \tag{22}$$

The equation of Duhem-Margules for the partial vapor pressures of a binary mixture is a form of equation (21). It will also be noticed that the equations derived in section (1) for a pure substance are special forms of these equations for a one-component system.

By making the two chambers of our engine infinite in volume and removing only one constituent we can obtain the following equations for the partial vapor pressure or osmotic pressure referred to *one constituent alone.*

$$(\partial p_A/\partial P)_{N,T} = V_A/v_A. \quad (23) \qquad (\partial \Pi_A/\partial P)_{V,T} = -\bar{V}_A/V_A. \quad (23a)$$

$$(\partial p_A/\partial T)_{N,P} = L_A/v_A T \quad (24) \qquad (\partial \Pi_A/\partial T)_{N,P} = -\bar{D}_A/V_A T. \quad (24a)$$

The absence of an equation for one constituent, corresponding to equation (15), will be noticed. Thermodynamics is incapable of yielding any information concerning the changes in the partial vapor pressure (or osmotic pressure) of one constituent of a mixture, with a change in the composition of the mixture, other than the information contained in equation (15).

Since $\bar{V}_A$ may be either positive or negative,[7] the partial vapor pressure of a constituent of a mixture, unlike the vapor pressure of a pure substance (see page 472), may be in some cases increased and in others decreased by increasing the total pressure on the mixture. L_A, the partial molecular heat of vaporization of any constituent, A, is the heat absorbed when one mol of A is vaporized reversibly from an infinite amount of the mixture. If the vapor obeys the perfect gas laws equation (24) becomes

$$(\partial \ln p_A/\partial T)_{N,P} = (L_A - D_A)/RT^2, \qquad (25)$$

where L_A is the molecular heat of vaporization of the *pure liquid* A, and D_A is the heat *absorbed* when one mol of liquid A is mixed with an infinite amount of the mixture. $-D_A$ is obviously the ordinary molecular *heat of dilution* of a solution with one of its components, A. The equation now contains only quantities which can be readily measured.

In a similar way equation (24*a*) for the *temperature coefficient of osmotic pressure* can be put in a more practical form if we replace $\bar{D}_A$ by $(D_A - \Pi_A V_A)$, which is equal to it by the First Law. If we choose to refer the heat of dilution to *unit volume* of solvent instead of to one mol we have[8] $q = D_A/V_A$ and equation (24*a*) assumes the familiar form of the Helmholtz equation

$$(\partial \Pi_A/\partial T)_{P,N} = (\Pi - q)/T. \qquad (26)$$

5. Chemical Equilibrium: A. Homogeneous.

Let us consider any chemical equilibrium, expressed by the equation

$$a\text{A} + b\text{B} + \ldots \rightleftarrows m\text{M} + n\text{N} + \ldots \qquad (27)$$

in which *a* mols of the substance A react with *b* mols of the substance B, etc., to form *m* mols of the substance M and *n* mols of the substance N, etc. The substances entering into the reaction are in equilibrium with each other in any homogeneous phase and there may or may not also be present in the phase one or more other substances which do not take part in the reaction: a solvent or an indifferent gas, for example. As in the preceding section the composition of the phase is represented by the equation

$$N_A + N_B + \ldots + N_M + N_N + \ldots + N_1 + N_2 + \ldots = 1 \quad (28)$$

where N_X is the mol fraction of the constituent X, numercial subscripts referring to substances which do not take part in the chemical equilibrium.

Our problem is to determine in what direction and to what extent the chemical equilibrium is displaced by, (1) increasing the concentration (*i. e.*, the mol fraction) of one of the reacting substances, (2) increasing the total pressure on the phase, and (3) increasing the temperature of the system. In deriving our fundamental equations, it will be simpler to fix our attention chiefly upon some particular phase, and we shall choose a gaseous phase, which, in addition to the reacting substances, contains also an indifferent gas which we shall call constituent, 1. It would correspond to a solvent if we were dealing with a liquid or solid solution.

[The treatment of chemical equilibrium in a homogeneous liquid or solid phase is quite analogous, it being simply necessary to replace partial gas pressure p_X by the osmotic pressure Π_X. It will be sufficient, therefore, in the following treatment, to indicate parenthetically (in brackets) the necessary changes in the process and the corresponding equations for these cases.]

Arrangement of the Engine.—We shall make use of the engine shown in Fig. 2. The arrangement is as follows:

Chamber **E**: Filled with the gaseous mixture as described above, the composition of the mixture being represented by the equation

$$N_A + N_B + \ldots + N_M + N_N + \ldots + N_1 = 1.$$

The substances A, B. , M, N. . are in chemical equilibrium as expressed by the equation

$$aA + bB + \ldots \rightleftarrows mM + nN + \ldots$$

The partial pressures of the substances taking part in the equilibrium act through suitable semipermeable membranes against the pistons as follows: p_A against piston **A**, p_B against piston **B**, p_M against piston **M** and p_N against piston **N**. The total pressure on the system is applied by means of piston **D**.

Chamber **E′**: Analogous in every respect to chamber **E** except that the equilibrium has been slightly displaced by some cause so that the partial pressures from this chamber have become $p_A + dp_A$ against piston **A′**, $p_B + dp_B$ against piston **B′**, etc.

[For a liquid (or solid) phase in the chamber, the cylinders are filled with the pure substances A, B, M, N, etc., in the liquid (or solid) state and the pressures on the pistons are osmotic pressures, Π_A and $\Pi_A + d\Pi_A$, Π_B and $\Pi_B + d\Pi_B$, etc.]

The operation of the engine consists in the movement of pistons **AA′**

and **BB′** toward the left until a mols of A and b mols of B have been forced into **E** and drawn out of **E′**; and the simultaneous movement of pistons **MM′** and **NN′** toward the right, removing m mols of M and n mols of N from **E** (as fast as they are formed by the reaction of A and B which are being introduced by pistons **AA′** and **BB′**) and forcing them into **E′** (as fast as they are required to replace, by reaction, the A and B which are being removed by pistons **AA′** and **BB′**). The equilibrium is not disturbed in either chamber. The work done by pistons **AA′**, **BB′**, **MM′** and **NN′** is

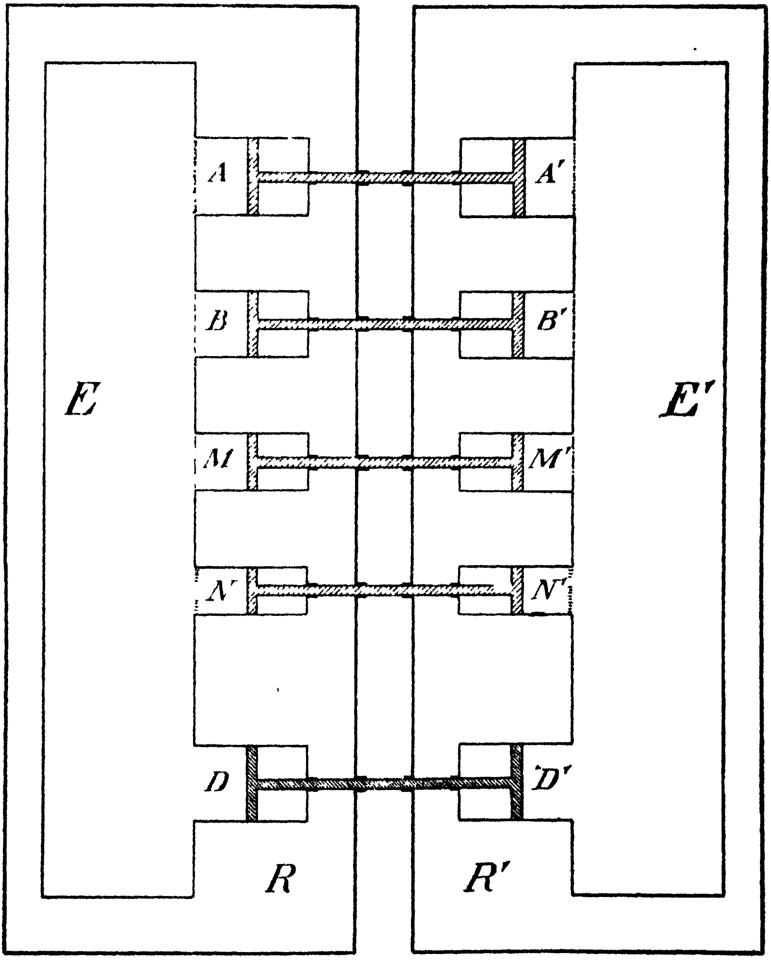

Fig. 2.

$$av_A dp_A + bv_B dp_B + \ldots - mv_M dp_M - nv_N dp_N - \ldots,$$

or more briefly,

$$\Sigma\pm av_{\mathrm{A}}dp_{\mathrm{A}} \quad [\text{for liquid or solid, } \Sigma\mp aV_{\mathrm{A}}d\Pi_{\mathrm{A}}].$$

The ± sign indicates that terms relating to the reacting substances are to be taken with a positive sign and those relating to the products of the reaction with a negative sign.

By the Second Law (Theorems I and II), this work is equal to (1) zero, or (2) QdT/T according as the displacement of the equilibrium in chamber **E′** is brought about by changing (1) the composition, or the total pressure, or (2) the temperature. We shall consider each effect separately.

The Composition and Pressure Coefficients (P, T = *const. or* N, T = *const*).—Keep the *total pressure* and the temperature in **E** and **E′** the same and displace the equilibrium in **E′** by changing the mol fraction of (say) A from N_{A} to $N_{\mathrm{A}} + dN_{\mathrm{A}}$; *or*, keep the *composition* and temperature the same in both **E** and **E′** and change the total pressure on **E′** from P to $P + dP$ by means of piston **D′**. In either case the operation of the engine gives us at once the equation

$$av_{\mathrm{A}}dp_{\mathrm{A}} + bv_{\mathrm{B}}dp_{\mathrm{B}} + \ldots - mv_{\mathrm{M}}dp_{\mathrm{M}} - nv_{\mathrm{N}}dp_{\mathrm{N}} - \ldots = 0 \quad (29)$$

or

$$\left(\frac{\Sigma\pm av_{\mathrm{A}}\partial p_{\mathrm{A}}}{\partial N_{\mathrm{A}}}\right)_{P,T} = 0 \quad (30) \qquad \left[\left(\frac{\Sigma\mp aV_{\mathrm{A}}\partial\Pi_{\mathrm{A}}}{\partial N_{\mathrm{A}}}\right)_{P,T} = 0 \quad (30a)\right.$$

$$\left(\frac{\Sigma\pm av_{\mathrm{A}}\partial p_{\mathrm{A}}}{\partial P}\right)_{N,T} = 0 \quad (31) \qquad \left.\left(\frac{\Sigma\mp aV_{\mathrm{A}}\partial\Pi_{\mathrm{A}}}{\partial P}\right)_{N,T} = 0 \quad (31a)\right]$$

These equations contain everything which thermodynamics alone is capable of teaching us concerning a chemical equilibrium at constant temperature. To proceed further it is necessary to know the functional relation between p and v for the system under consideration. To illustrate, let us assume that this relation is $pv = RT$, *i. e.*, the perfect gas law. Putting $v_{\mathrm{X}} = RT/p_{\mathrm{X}}$ for each substance in equation (30), the equation becomes

$$RT\,d\ln\frac{p_{\mathrm{A}}^{a}\cdot p_{\mathrm{B}}^{b}\cdots}{p_{\mathrm{M}}^{m}\cdot p_{\mathrm{N}}^{n}\cdots} = 0. \quad (32)$$

This equation can obviously only be true if

$$\frac{p_{\mathrm{A}}^{a}\cdot p_{\mathrm{B}}^{b}\cdots}{p_{\mathrm{M}}^{m}\cdot p_{\mathrm{N}}^{n}\cdots} = const. = K_{p}, \quad (33)$$

which is the mathematical formulation of the law of chemical mass action in terms of partial pressures. It can be expressed in terms of *mol fractions* or *volume concentrations* by substituting $p_{\mathrm{X}} = N_{\mathrm{X}}P$ or $p_{\mathrm{X}} = C_{\mathrm{X}}RT$, respectively, in equation (33), giving

$$\frac{N_{\mathrm{A}}^{a}\cdot N_{\mathrm{B}}^{b}\cdots}{N_{\mathrm{M}}^{m}\cdot N_{\mathrm{N}}^{n}\cdots} = K_{p}P^{\Delta x}(= K_{N} \text{ for constant } P), \quad (34)$$

and

$$\frac{C_A^a \cdot C_B^b \cdots}{C_M^m \cdot C_N^n \cdots} = K_p(RT)^{\Delta x} = K_C, \qquad (35)$$

where Δx—the change in the number of mols which results from the reaction—is written for $(m + n + \ldots - a - b - \ldots)$.

It is evident, from the preceding, that the Law of Mass Action for a gaseous phase (*i. e.*, equation (33)) expresses the condition of chemical equilibrium *only* for a system in which the substances taking part in the reaction are all perfect gases. And of the perfect gas laws only those of Boyle and Avogadro are involved. It is not essential that the law of Gay-Lussac (*i. e.*, $p = kT$) be obeyed. To state, therefore, that any chemical equilibrium (in a gaseous phase or dilute solution) does not obey the Mass Action Law is simply to state that the pressure (gaseous or osmotic) of at least *one* of the substances concerned in the equilibrium does not obey the law of Boyle-Avogadro. Notwithstanding the fact that this law has been shown to be both a necessary and sufficient condition for the validity of the Law of Mass Action, the belief seems still to be held in some quarters that the latter law may after all have a wider and more general application. T. B. Robertson, for example, in a recent paper,[8] considers the conditions for chemical equilibrium in a system in which the equation $p(v - d) = RT$ is obeyed instead of the perfect gas law. He concludes that such a system must *also* obey the Law of Mass Action.[9] This conclusion must be regarded as erroneous. The equation $p(v - d) = RT$ does *not* lead to the Mass Action Law but to quite a different expression, as will be evident by substituting $v = RT/p + d$, in equation (30) and integrating. This gives the relation

$$RT \ln p_A^a \cdot p_B^b \cdots / p_M^m \cdot p_N^n \cdots = const. - \Sigma \pm a p_A d_A \qquad (36)$$

in which the last term represents the series

$$a p_A d_A + b p_B d_B + \ldots - m p_M d_M - n p_N d_N - \ldots$$

Similarly for *each* equation of state there is a *corresponding* law of chemical equilibrium but the Law of Mass Action belongs *only* to systems obeying the Boyle-Avogadro law.

The Temperature Coefficient $(P,\ N = const.)$.—Keep the composition and total pressure the same in **E** and **E**′ and displace the equilibrium in **E**′ by changing the temperature of **R**′ from T to $T + dT$. The operation of the engine gives us the equation

$$a v_A dp_A + b v_B dp_B + \ldots - m v_M dp_M - n v_N dp_N - \ldots = Q dT/T \qquad (37)$$

or

---

[8] *J. Physic. Chem.*, 10, 522 (1907).

[9] This conclusion seems to have been accepted by other investigators, apparently without question. It is quoted by the Earl of Berkeley (*Proc. Roy. Soc.*, A79, 131 (1907)) in support of certain conclusions regarding the application of van der Waals' equation to solutions and it is even beginning to appear in the text-books. See, for example, the last edition of Morgan's "Elements of Physical Chemistry," p. 239.

$$\left(\frac{\Sigma^{\pm} a v_A \partial p_A}{\partial T}\right)_{P,[N-f(T)]} = \frac{Q_p}{T} \quad (38) \quad \left[\left(\frac{\Sigma^{\pm} a V_A \partial \Pi_A}{\partial T}\right)_{P,[N-f(T)]} = \frac{Q_\pi}{T} \quad (38a)\right]$$

where Q_p is the heat *evolved* by the reaction when it proceeds from left to right according to equation (27) and does the maximum external work. If we assume the *perfect gas law* this equation becomes

$$(\partial \ln K_p/\partial T)_{P,N} = Q_p/RT^2, \tag{39}$$

where K_p is defined by equation (33). We may substitute, $K_p = K_c(RT)^{\Delta x}$ (equation (35)) and $Q_p = U - \Delta xRT$ (by the first law of thermodynamics) and obtain the familiar equation of van't Hoff,

$$d\ln K_c/dT = U/RT^2, \tag{40}$$

where K_c is defined by equation (35) and U, the change in total energy, is the heat evolved when the reaction takes place (from left to right) without external work.[10]

6. Chemical Equilibrium. B. Heterogeneous.

The Composition Coefficient (*P*, *T* = *const.*).—The arrangement and operation of the engine for this case are in general exactly the same as for the corresponding case of homogeneous equilibrium, except that

---

[10] General Equations.—The results just obtained for the effects of composition, pressure and temperature can, if desired, be expressed in a single general equation. For example, suppose we wish to find a general equation by means of which K_N can be calculated for a given gaseous mixture at any temperature or pressure. We have the general expression

$$d\ln K_N = (\partial \ln K_N/\partial P)_T dP + (\partial \ln K_N/\partial T)_P dT. \tag{41}$$

From equation (34), by taking the logarithm of both sides and differentiating, we obtain

$$(\partial \ln K_N/\partial P)_T = \Delta x/P. \tag{42}$$

From equations (34) and (39) we obtain

$$(\partial \ln K_N/\partial T)_P = (\partial \ln K_p/\partial T)_P = Q_p/RT^2. \tag{43}$$

But by the first law of thermodynamics,

$$Q_p/RT^2 = U + \Delta xRT/RT^2 = U/RT^2 + \Delta x/T \tag{44}$$

and

$$U = U_0 + \Sigma(ah_A)T. \tag{45}$$

Consequently,

$$(\partial \ln K_N/\partial T)_P = U_0/RT^2 + \Sigma(ah_A)/RT + \Delta x/T \tag{46}$$

and combining with (41) and (42) we obtain finally,

$$d\ln K_N = \Delta x dP/P + U_0 dT/RT^2 + [\Sigma(ah_A) + R\Delta x]dT/RT \tag{47}$$

which, on integration, yields

$$\ln K_N = \ln I + \Delta x \ln P + \frac{(\Sigma(ah_A) + R\Delta x)}{R}\ln T - \frac{U_0}{RT} \tag{48}$$

or, written in the exponential form

$$K_N = IT^b P^{\Delta x} e^{-\frac{U_0}{RT}} \tag{49}$$

in which I is the integration constant and b is written for $(\Sigma(ah_A) + R\Delta x)/R$. This is Gibbs' formula for gas dissociation, and has, I believe, heretofore never been derived except by the use of Gibbs' thermodynamic potential. Van Laar even goes so far as to state (*Sechs Vorträge*, p. 69) that it is not possible to derive it in any other way.

substances present in a second state of aggregation are not removed from one chamber and forced into the other during the operation of the engine, but are simply allowed to vaporize (or dissolve) in one chamber and condense (or precipitate) in the other as the reaction progresses. This, of course, necessitates the movement of the pressure piston, **DD′**, through the corresponding volume change; but since it moves under zero pressure it does no work, and the differential equation obtained is therefore identical with the one for homogeneous equilibrium *with the omission of all terms referring to substances present in a second state of aggregation.* These omissions may be indicated by placing the symbol $\textcircled{2}$ inside the summation sign. Thus in place of equation (30) [and (30*a*)] we have:

$$\left(\frac{\Sigma_{\textcircled{2}} a v_A \partial p_A}{\partial N_A}\right)_{P,T} = 0 \quad (50) \qquad \left[\left(\frac{\Sigma_{\textcircled{2}} a V_A \partial \Pi_A}{\partial N_A}\right)_{P,T} = 0\right] \quad (50a)$$

It is customary to derive the laws of heterogeneous chemical equilibrium, from the corresponding laws of homogeneous equilibrium—the Mass Action Law for example—by assuming that the pressures or concentrations of substances present in a second state of aggregation are constants. While this gives the correct result and is a convenient aid to the memory, as a general method of proof it must be condemned, because the assumption upon which it is based is not only unnecessary but is apt to be misleading. This can be illustrated by considering a specific example.

The law of the constancy of the solubility product for difficultly soluble substances which dissociate in solution is almost invariably derived by first assuming the Mass Action Law and then assuming that the concentration of the undissociated portion is a constant so long as an excess of the solid phase is present. Now in the case of aqueous solutions of strong electrolytes, Stieglitz has recently called attention to the fact that since the Mass Action Law does not hold even approximately for these substances, any derivation based upon this law cannot be applied to their solutions. He therefore concludes[11] that there is no theoretical basis for the Solubility Product Law in the case of strong electrolytes.

This criticism of the method of derivation in the case of strong electrolytes is quite justified, but the conclusion which is drawn regarding the lack of theoretical foundation for the law in these cases is unjustified. In order to derive the Solubility Product Law it is not only unnecesssary to assume the Mass Action Law but it is not even necessary to know what the law is which regulates the equilibrium between the dissociated and undissociated portions of the dissolved solute. This can be made clear by applying the engine as indicated above (p. 487) to a saturated solution of a solute, BC for example, which dissociates in solution according to the equation

---

[11] Stieglitz, THIS JOURNAL, 30, 954 (1908). After recalculating Arrhenius' solubility data and finding good agreement with the Solubility Product Law, he concludes: "In view of these facts and also in view of the results of the complete calculation of Arrhenius' data on the solubility of the silver salts, which removed the last *theoretical* foundation for the solubility product constant, we may well consider it for the present to be an approximate empirical principle."

$$BC \rightleftarrows B + C.$$

We obtain at once the equation[12]

$$V_B d\Pi_B + V_C d\Pi_C = 0 \qquad (51)$$

where $d\Pi$ in both cases may be *either* $(\partial\Pi/\partial N_B)dN_B$ or $(\partial\Pi/\partial N_C)dN_C$.

If A and B are "normal solutes" and the solution is sufficiently dilute it can be readily shown that equation (51) takes the form

$$C_{B'} \cdot C_{C'} = const. = (\alpha_0 S_0)^2 \qquad (53)$$

---

[12] If the operation is carried out in the manner described in the preceding sections, the cylinders of the engine will contain pure liquid B (resp. C) and π_B (resp. π_C) will denote the difference in pressure upon the solution and the pure liquid B (resp. C) which is necessary to establish equilibrium; or as we have called it (see p. 478), "the osmotic pressure referred to B (resp. C) as the solvent." In case B and C happen to be ions, some difficulty will doubtless arise in the minds of some readers as to the validity of a process which makes use of a cylinder filled with pure liquid ion. If so, the arrangement of the engine can be easily changed so that the cylinders shall contain *solutions* of the ions separated from the chambers by membranes permeable only to the ion in question. The pistons then would be permeable only to the solvent and the osmotic pressure (π_B' resp. π_C') would be the *ordinary* osmotic pressure of the solute, in the present instance an ion. Thus, looking at Fig. 3 a moment, the movement of piston BB′ toward the left would necessitate the flow of pure solvent toward the right through piston B′ into cylinder B′ where it would dilute the solution of B-ion contained in this cylinder. But this solution would then no longer be in equilibrium with the solution in chamber E′ and the ion B^+ would pass from E′ through the semipermeable membrane into cylinder B′ until the equilibrium was restored. The motion of piston BB′ toward the left would therefore result in drawing B^+-ion out of chamber E′ and forcing it into Chamber E, just as in the general case where the cylinders are filled with the pure liquids. Piston CC′ would do the same for C-ion, so that we would obtain the equation

$$V_{B'} d\pi'_{B'} + V_{C'} d\pi'_{C'} = 0, \qquad (52)$$

which is identical in form with equation (51) above and for dilute solutions leads to the same result when integrated. Thus if the ions are "normal solutes" and the solution is "sufficiently dilute," we can write for each ion

$$\pi' = CRT,\ d\pi' = RTdC \text{ and } V = 1/C$$

which gives us

$$RTd \ln C_{B'} \cdot C_{C'} = 0,$$

or

$$C_{B'} . C_{C'} = \text{const} = (\alpha_0 S_0)^2. \qquad (53)$$

The exact significance of the term "normal solute" will be treated more fully in a future communication, in which a set of equations for solutions will be derived without making any assumption regarding the concentration of the solution. The equations for "dilute solutions" which are developed in the present paper will there be shown to be only special cases of a more general set of equations for solutions of any concentration. For the present the term "normal solute" may be understood to refer to any solute "whose osmotic pressure in dilute solution obeys the gas laws."

which is the Solubility Product Law. S_0 and α_0 are, respectively, the solubility of BC in the pure solvent and its degree of dissociation in this solution. Since the Solubility Product Law is found to hold, at least approximately, for solutions of strong electrolytes of the uni-univalent type, it is evidence that the ions in these solutions are approximately "normal solutes" (*i. e.*, their osmotic pressures are proportional to their concentrations in dilute solution), and that the deviations from the Mass Action Law for strong electrolytes must be attributed *chiefly* to the failure of the Boyle-Avogadro law in the case of the unionized molecules. This conclusion has been pointed out recently by A. A. Noyes,[13] who offers a very suggestive provisional hypothesis to account for the abnormal behavior of the unionized molecules in such solutions.

The Pressure Coefficient (N, T = *const.*).—In the case of heterogeneous equilibrium, when piston **DD′** applies a pressure P to chamber **E** and $P + dP$ to chamber **E′**, the operation of the engine is accompanied by a motion of this piston through the volume change which results from the chemical reaction and a work term, ΔVdP, appears in the equation which was absent in the corresponding case of homogeneous equilibrium (q. v. p. 484). Otherwise the operation remains the same and the final equation obtained is in all other respects identical with the corresponding one for homogeneous equilibrium, but *with the omission of all terms referring to substances present in a second state of aggregation.* Thus, corresponding to equation (31) [and (31*a*)] for homogeneous equilibrium, we obtain in the case of heterogeneous equilibrium the equation

$$\left(\frac{\Sigma_{(2)}^{\pm} av_A\partial p_A}{\partial P}\right)_{N,T} = \Delta V \quad (54) \text{ and } \left[\left(\frac{\Sigma_{(2)}^{\pm} aV_A\partial \Pi_A}{\partial P}\right)_{N,T} = \Delta V_\pi\right]. \quad (54a)$$

The exact meaning of ΔV is clearly evident from the operation of the engine. It is equal to the increase in the total reaction volume of all substances present in a second state of aggregation, which results when the reaction proceeds from left to right in the sense of equation (27). This can be illustrated by considering some specific examples.

Suppose the reaction under consideration is

$$a\text{A} + b\text{B} \rightleftarrows m\text{M} + n\text{N} \qquad (55)$$

in which A and M are gases and B and N solids. Applying equation (54) to this case, or better, using the engine directly, we obtain the equation

$$av_A dp_A - mv_M dp_M = \Delta V dP. \qquad (56)$$

ΔV here is obviously equal to the reaction volume of N minus the reaction volume of B. Now the reaction volume of N is nV_N, where V_N is the molecular volume of *solid N* under the pressure P. Similarly the reaction volume of B is bV_B, so that $\Delta V = nV_N - bV_B$. If we assume the perfect gas laws for A and M, equation (56) becomes

---

[13] A. A. Noyes, THIS JOURNAL, 30, 351 (1908).

$$RTd\ln p_A^a/p_M^m = (nV_N - bV_B)dP \tag{57}$$

or

$$(\partial \ln K_p/\partial P)_{T,N} = (nV_N - bV_B)/RT. \tag{58}$$

Another example: Let us consider a solid BC in contact with its saturated solution in which it exists in a state of partial dissociation, the equilibrium between the solid and its dissociation products in solution being expressed by the equation

$$\mathrm{BC} \rightleftarrows \mathrm{B} + \mathrm{C}. \tag{59}$$

How will an increase of pressure affect this equilibrium? Operate the engine so that solid BC dissolves in chamber **E′**, under the pressure $P + dP$ and its dissociation products are removed osmotically and an equivalent amount forced into chamber **E**, where they at once combine to form solid BC under the pressure P. This gives us the equation

$$V_B d\Pi_B + V_C d\Pi_C = \Delta V dP, \tag{60}$$

in which ΔV is the decrease in volume which results when one reaction weight (= one mol in this case) of solid BC dissolves in its saturated solution. If B and C are "normal solutes"[12] and the solution is dilute it can be shown that equation (60) becomes

$$RTd\ln(\alpha_0 S_0)^2 = \Delta V dP \tag{61}$$

or

$$[\partial \ln(\alpha_0 S_0)^2/\partial P]_{N,T} = \Delta V/RT \tag{62}$$

in which S_0 is the solubility of BC (expressed as mols per 1000 grams of solvent) under the pressure P and α_0 is its degree of dissociation in the saturated solution. This is obviously an equation giving the pressure coefficient of the logarithm of the solubility product.[19]

The Temperature Coefficient (N, P, = *const.*).—From what has been said in the preceding portions of this section, it is evident that the operation of the engine for this case gives us the general equation

$$\left(\frac{\Sigma \overset{+}{\underset{\smile}{(2)}} av_A \partial p_A}{\partial T}\right)_{N,P} = \frac{QdT}{T} \quad (63), \quad \left[\left(\frac{\Sigma \overset{+}{\underset{\smile}{(2)}} aV_A \partial \Pi_A}{\partial T}\right)_{N,P} = \frac{Q_\pi dT}{T}\right]. \quad (63a)$$

We will reserve until some future time the further discussion of the general case, and will consider here a specific example, the temperature coefficient of the solubility product for an electrolyte.

---

[19] In case B and C happen to be ions we may modify the operation of the engine as explained in note (12). In this case we shall, however, obtain the same final equations (*i. e.*, equation (62)).

Let us apply the engine directly: We have in both chambers a saturated solution of an electrolyte BC in contact with an excess of the solid. Chamber **E** is at $T°$ and chamber **E′** at $T + dT°$. The operation of the engine consists in the solution of one mol of solid BC in chamber **E′**, accompanied by its simultaneous removal osmotically in the form of solutious of B-ion and C-ion by means of pistons **B′** and **C′**, as described in note 12. The reverse process, of course, occurs in chamber **E**. The equation for the operation is (cf. eq. 52).

$$V_{B'}d\Pi'_{B'} + V_{C'}d\Pi'_{C'} = QdT/T \tag{64}$$

If the ions as "normal solutes" and the solution is "sufficiently dilute" we can write for each ion, $\Pi' = CRT$, $d\Pi' = RTdC + RCdT$, and $V = 1/C$,
which gives

$$RTd\ln C_{B'}.C_{C'} + 2RdT = QdT/T, \tag{65}$$

or

$$RT^2d\ln(\alpha_0.S_0)^2 = (Q - 2RT)dT, \tag{66}$$

or

$$(\partial\ln(\alpha_0.S_0)^2/\partial T)_{P,N} = U/RT^2. \tag{67}$$

U, the increase in internal energy, is equal to the heat absorbed when a system composed of one mol of solid BC and $1000/2\alpha_0.S_0$ grams of pure solvent, both under the pressure P and at the temperature T, changes, without the production of any work, into a system composed of a solution of BC in which the solute exists only in the form of its ions. Such a solution cannot be obtained in reality but the corresponding heat effect can be measured, which is all that is necessary. It is perhaps worth while to consider a numerical example illustrating the use of equation (67).

Let us compare the directly measured value of U with the value calculated by means of the expression

$$2RT^2(d\ln\alpha_0/dT + d\ln S_0/dT) = U, \tag{68}$$

in the case of orthonitrobenzoic acid. The value of U for this acid obtained by calorimetric measurements at 20° is 4040 ± 100 cal.[14] The value of $(d\ln S_0/dT)_{20°}$ has been determined by Noyes and Sammet[15] and found to be 0.03335. From their conductivity measurements at 15° and 25°, we obtain $\alpha_{15°} = 0.386$ and $\alpha_{25°} = 0.311$, whence $\Delta\ln\alpha/\Delta t$ for this temperature interval comes out —0.0216, which we shall take as the value of $(d\ln\alpha_0/dT)_{20°}$. Adding these values we obtain $d\ln(\alpha_0 S_0)/dT = 0.0118$, which, when multiplied by $2RT^2$ (*i. e.*, $2 \times 1.98 \times 293 \times 293$) gives 4020 Cal. as the calculated value of U, which is in good agreement with the directly measured value.

---

[14] From a determination made in this laboratory by Mr. D. A. MacInnes. We hope to extend this investigation in the near future and will therefore defer the description of the method until its completion.

[15] Noyes and Sammet, *Z. physik. Chem.*, 43, 529 (1903).

In interpreting their experimental results, Noyes and Sammet use the equation of van't Hoff[16] for the temperature coefficient of the *total* concentration of a saturated solution of an ionized solute, namely,

$$d\ln iS/dT = L/iRT^2, \qquad (69)$$

in which i ($= 1 + \alpha$) is the van't Hoff coefficient. We would have obtained this equation, if in using the engine we had removed osmotically from chamber E′ not simply one mol of the solute in the form of its ions but one mol of the solute in the form of both ions and undissociated molecules, in the proportions in which they exist together in the saturated solution. Then, in order to obtain the equation in the above form, we should have had to assume that the undissociated molecules were "normal solutes" as well as the ions. In other words, the van't Hoff equation involves an unnecessary number of assumptions. It is an equation which can be obtained by combining two equations, one involving only the ions (*i. e.*, equation (67)) and another similar one involving only the undissociated molecules.

The recent work of A. A. Noyes and his associates[17] has shown us the necessity for differentiating between ions and undissociated molecules with regard to their behavior as solutes. There is all the more reason for doing this since the assumption that they behave alike in this respect is quite unnecessary in the majority of cases. All of our equations for solution, which contain the van't Hoff factor i, are derived on the assumption that both ions and undissociated molecules are "normal solutes." Consequently, if a given equation is found to be in agreement with the results of experiment, it does not necessarily mean that this assumption is correct, for agreement might still occur if both the ions and undissociated molecules deviated, but in opposite directions, from the behavior of the normal solute. If the equation is not in agreement with the results of experiment, it does not tell us whether the disagreement is due to the behavior of the ions or the undissociated molecules, or both. And yet it is quite possible to decide this question, for in nearly every case the equation containing the van't Hoff i can be broken up into two simpler equations, one of which involves only the ions and the other only the undissociated molecules. An example of this occurs in the case of orthonitrobenzoic acid, described above. Noyes and Sammet found that the van't Hoff equation (eq. (69)) *was not* in agreement with the results of their experiments with this acid. We have seen that equation (67), which involves only the ions, *is* in good agreement with the experimental results. Consequently the deviation from the van't Hoff equation must be ascribed, for the most part at any rate, to the abnormal behavior of the undissociated portion. Whether it is to be attributed to the partial association of the unionized molecules (as Noyes and Sammet suggest) or to the presence of two isomeric forms of these molecules is not yet certain.[18]

---

[16] van't Hoff, *Z. physik. Chem.*, 17, 147, 546 (1895).

[17] Carnegie Inst. Pub., No. 63.

Before leaving this subject attention should be called to the fact that we have in equation (67) a very valuable method for studying the behavior of ions (apart from the unionized molecules) with respect to the Gay-Lussac law for the effect of temperature upon osmotic pressure in dilute solutions.[18]

7. Electromotive Force.

The Perfect Thermodynamic Engine is generally applicable to the derivation of all types of electromotive force equations which are based directly upon the Second Law In the present paper, however, we shall confine the consideration to the electromotive force of concentration cells. The type of engine used is shown in Fig. 3. It differs from the preceding forms only by the addition of the parts **W** and $\eta\eta'$. **W** is a device which permits the easy passage of ions but which resists any mass flow of the solution from one chamber to the other, thus permitting a difference of pressure to be maintained in the two chambers, if desired. η and η' are two reversible electrodes which can be connected with each other (through a suitable compensating external E. M. F. to ensure operation under equilibrium) by means of the key **K**.

Concentration Cells (T, P = *const*.).—(*a*) *The Nernst Equation.*—As an example of this case let us consider a simple concentration cell with reversible silver electrodes and with silver nitrate as the electrolyte. Using the engine shown in Fig. 3, omitting cylinder **AA'**, and with temperature of **R** and **R'** = T, and pressure against **D** and **D'** = P, the arrangement of the engine is as follows:

Chamber **E**: Filled with a solution of silver nitrate of concentration C and provided with a reversible silver electrode η which has a potential E. Cylinder **B** contains a solution of silver ion which is in equilibrium, through the semipermeable membrane, with the silver ion in the chamber. Piston **B**, which is impermeable only to silver ion, is under the "osmotic pressure" $\Pi'_{Ag^{\cdot}}$. Cylinder **C** is arranged similarly with respect to NO_3-ion, the "osmotic pressure" against piston **C** being $\Pi'_{NO'_3}$.

Chámber **E'**: Similar to **E** except that the solution has concentration $C + dC$, the potential of the electrode η' is E + dE and the osmotic pressures are $\Pi'_{Ag^\cdot} + d\Pi'_{Ag^\cdot}$ against piston **B′** and $\Pi'_{NO'_3} + d\Pi'_{NO'_3}$ against piston **C′**.

---

[18] We hope to pursue this question further experimentally in this laboratory, as well as the general question of the temperature coefficients of the osmotic pressures of ions as distinct from the unionized molecules.

To operate the engine, close the key **K** and allow one equivalent (F) of electricity to flow reversibly. The passage of this current is accompanied by the electrical transference of n_a equivalents of electrolyte from chamber **E′** to chamber **E** (*i. e.*, from cathode to anode). n_a is the ordinary or Hittorf transference number of the anion.[20] To compensate

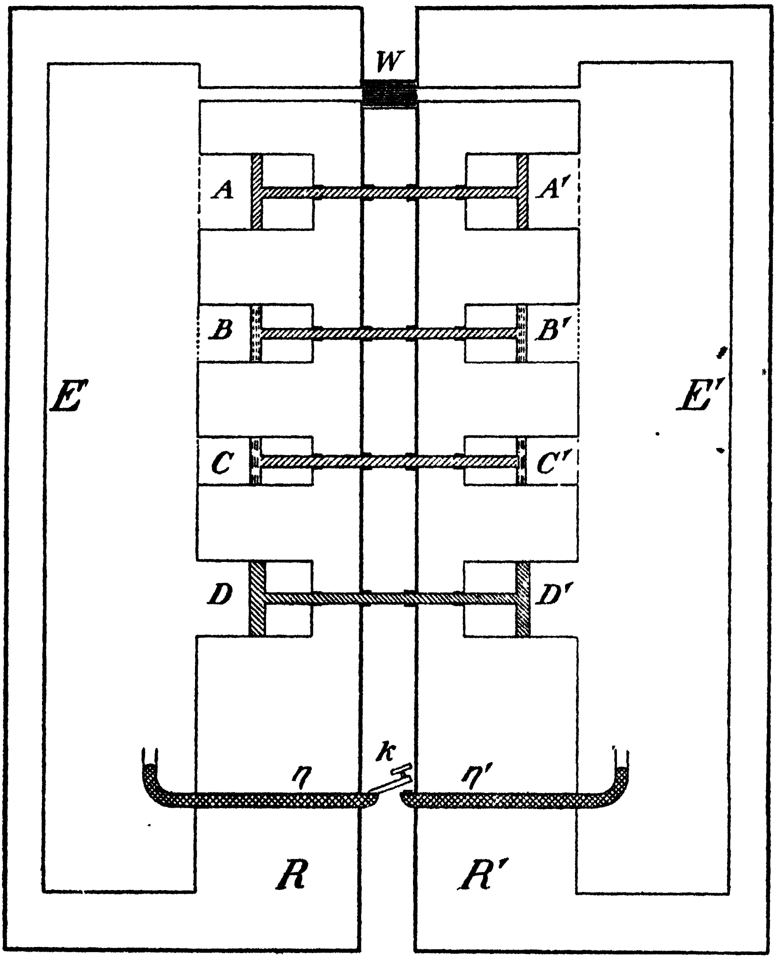

Fig. 3.

---

[20] In general, both solvent and electrolyte are transferred by the current. For the present purpose it is not necessary to differentiate between these two factors but only to know the *total* effect referred to solute alone, and this is expressed by the ordinary Hittorf transference number. An equation involving the "true transference number" (see Washburn, THIS JOURNAL, 31, 323 (1909)) can be readily obtained by

for this effect and maintain equilibrium, pistons **BB′** and **CC′** move reversibly toward the right removing n_a mols of each ion from **E** and forcing them into **E′**. By the Second Law the total work is equal to zero, or

$$FdE = n_a[V_{Ag^{\cdot}}d\Pi'_{Ag^{\cdot}} + V_{NO_3'}d\Pi'_{NO_3'}]. \qquad (70)$$

If we assume the ions to be normal solutes and the solution dilute, this equation becomes

$$dE = (2n_aRT/F)d\ln C_{Ag^{\cdot}}. \qquad (71)$$

In order to integrate we need to know n_a as a function of $C_{Ag^{\cdot}}$. If we assume it to be independent of the concentration we obtain the Nernst equation on integrating.

$$E - E' = \Delta E = (2n_aRT/F)\ln C_{Ag^{\cdot}}/C'_{Ag^{\cdot}}. \qquad (72)$$

If $C_{Ag^{\cdot}} = \alpha C$ and $\alpha = \Lambda_c/\Lambda_\infty$ this equation becomes

$$E - E' = \Delta E = (2n_aRT/F)\ln \Lambda_cC/\Lambda_{c'}C', \qquad (73)$$

in which Λ_c indicates the equivalent conductance of the solution at the concentration C.

It should be noticed that *this equation contains no assumption regarding the relation which exists between the ions and undissociated molecules in the solution.* It requires only that the ions be "normal solutes," the behavior of the undissociated molecules in this respect not being involved. Another important characteristic of the equation is the fact that *it is not influenced by errors in the value of the equivalent conductance at infinite dilution.* It offers therefore *another* method of studying the behavior of ions apart from their relation to the undissociated molecules (cf. page 489).

(*b*) *The Helmholtz Equation.*—Using the engine shown in Fig. 3 but omitting cylinders **BB′** and **CC′** the arrangement is as follows:

Chamber **E**: Filled with a solution of (say) HCl of any concentration C and provided with a reversible calomel electrode η having the potential E. The vapor pressure of HCl from the solution acts through the semipermeable membrane against piston **A** with a pressure p.

Chamber **E′**: The same as **E** except that the concentration of the solution is $C + dC$, the potential of η' is $E + dE$ and the vapor pressure acting against piston **A′** is $p + dp$.

The operation of the engine is evident and gives us at once the relation

$$FdE = n_Kvdp. \qquad (74)$$

If the vapor obeys the perfect gas law this becomes

$$dE = (n_KRT/F)d\ln p \qquad (75)$$

which on integration, assuming n_K const., gives the Helmholtz equation,

$$E - E' = (n_KRT/F)\ln p/p'. \qquad (76)$$

---

introducing into the engine a vapor piston by means of which solvent can be vaporized from one chamber and condensed into the other.

n_K is here the Hittorf transference number of the cation. Obviously an exactly similar equation can be obtained in terms of the partial vapor pressures of the *solvent* from the two solutions.

These two examples will be sufficient to illustrate the use of the engine in deriving E. M. F. equations. The requisite arrangement and operation of the engine for the derivation of pressure or temperature equations (*e. g.*, the Gibbs-Helmholtz equation) will be readily understood from the corresponding cases of vapor pressure, chemical equilibrium, etc., which have been described in the preceding pages.

8. The Colligative Properties of a Solution.

The quantities osmotic pressure, vapor-pressure lowering, freezing-point lowering, boiling-point raising,[21] etc., which lie at the basis of our methods of molecular weight determination in solution, have played such important rôles in the development of the modern theory of solutions, that a clear conception of the thermodynamic relations which connect them with one another is of fundamental importance. In many cases, the derivations of these relations which are given in the text-books contain the assumption that the solution is dilute and involve one of the laws of dilute solutions. Even in an elementary text, the only excuse that can be offered for introducing such assumptions is that the derivation of the exact relation is too complicated for the student to grasp at this stage. But even on such grounds, this procedure can scarcely be justified if it leaves the student with the idea that the relation between osmotic pressure and freezing-point lowering, for example, is in any way dependent upon the law which connects either of these quantities with the concentration. In the following pages it will be shown that by means of the thermodynamic engine the exact relations can be written down at once. These relations are, of course, differential equations. The method of integration varies with the nature of the solvent and the accuracy with which it is possible to measure the various quantities concerned. In the present paper the methods of integration will only be indicated briefly for some of the simplest cases.

The type of engine used is shown in Fig. 1. Both chambers are filled with the solution under investigation. Piston **AA′** is a "vapor piston," that is, as it moves toward the left, for example, it draws the vapor of the solvent out of chamber **E′** and condenses it into chamber **E**. Piston **BB′** is an osmotic piston. As it moves toward the left it allows solvent to enter chamber **E′** by passing through the semipermeable head **B′**, while at the same time solvent is removed in a similar manner from chamber **E**, the space behind the two piston heads being filled with pure solvent. Piston DD′ is the total pressure piston. It moves to the right or left during the operation of the engine whenever a volume change in the chambers renders it necessary, but since in the following treatment we shall deal always with a solution under constant external pressure (that of the atmosphere for example), this piston will move only under a pressure difference of zero. Consequently no work is involved in its motion and it will not be necessary to consider it at all during the operation of the engine.

---

[21] Following the suggestion of Ostwald, we shall call these quantities the colligative properties of the solution.

For the solution we will take any homogeneous liquid mixture of any number of constituents, A, B, C, etc. Since the terms solvent and solute are perfectly arbitrary for such a solution, let us regard A as the solvent and the other constituents as solutes.

Osmotic Pressure and Vapor Pressure (P, T = *const.*).—To ask the question, How does the vapor pressure of the solvent from any solution vary with the osmotic pressure? is equivalent to asking the question,[22] How does the vapor pressure of the pure liquid solvent vary with the total pressure upon it? and this relation has already been derived. It is equation (2) which may be written as follows (since by definition $d\Pi = -dP$):

$$(\partial p/\partial \Pi)_{P,T} = -V/v. \qquad (77)$$

In order to integrate we need only know v and V as functions of p and Π, respectively. Assuming the gas laws for the vapor we have $v = RT/p$. If V_0 is the molecular volume of the liquid under the pressure P (*i. e.*, when $\Pi = 0$, see p. 478) and α is its coefficient of compressibility between P and $P - \Pi$ ($\alpha = (V_0 - V)/V_0(P - \Pi - P)$), then $V = V_0(1 + \alpha\Pi)$. Substituting in equation (77) and integrating we have

$$RT\int d\ln p = -V_0\int(1 + \alpha\Pi)d\Pi,$$

or

$$RT\ln p = -V_0(\Pi + {}^1/_2\alpha\Pi^2) + RT\ln p_0,$$

in which the quantity p_0 in the integration constant is the vapor pressure of the pure solvent under the pressure P and at the temperature T. This gives us finally

$$\Pi + {}^1/_2\alpha\Pi^2 = -(RT/V_0)\ln p/p_0. \qquad (78)$$

In many cases the term containing α is negligible and by expanding the logarithm term into a series we can obtain a more convenient form for ordinary use:

$$\Pi \doteq \frac{RT}{V_0}\left[\left(\frac{p_0 - p}{p_0}\right) + {}^1/_2\left(\frac{p_0 - p}{p_0}\right)^2 + {}^1/_3\left(\frac{p_0 - p}{p_0}\right)^3 + \ldots\right] \qquad (79)$$

The ordinary equation for dilute solutions is obtained by neglecting all but the first term in the above series.

---

[22] See the definition of osmotic pressure, p. 478.

Osmotic Pressure and Freezing-point Lowering (P = *const.*).—The problem may be stated thus: How does the osmotic pressure of a solution change with the temperature at which the solution is in equilibrium with the pure solid solvent? The arrangement of the engine is as follows:

Chamber **E**: Filled with a solution in equilibrium with an excess of pure solid solvent and therefore at the temperature of its freezing point, T_F. The mol fraction of the solvent in the solution is N_A. The pure liquid solvent (in cylinder **B**) in equilibrium with the solution is under the osmotic pressure Π.

Chamber **E′**: Exactly as chamber **E** except the mol fraction of the solvent is $N_A + dN_A$, the freezing point $T_F + dT_F$ and the osmotic pressure $\Pi + d\Pi$.

$d\Pi$ in this instance is given by the expression

$$d\Pi = (\partial\Pi/\partial T)_N(\partial T_F/\partial N_A)_P dN_A + (\partial\Pi/\partial N_A)_T dN_A. \qquad (80)$$

To operate the engine allow one mol of solid solvent to melt in chamber **E′** and remove the resulting liquid osmotically with piston **BB′**. The reverse operation occurs in chamber **E′**. The work done by piston **BB′** is $-Vd\Pi$. The heat absorbed at the higher temperature (*i. e.*, from reservoir **R′**) is the molecular heat of fusion (L_F) of the solid solvent, under the pressure P, to form liquid solvent under the pressure $p - \Pi$. We have therefore by the Second Law

$$-Vd\Pi = L_F dT_F/T_F, \qquad (81)$$

or

$$(\partial\Pi/\partial T_F) = -L_F/VT_F. \qquad (82)$$

In this equation we can put $T_F = T_0 - \Delta t_F$, and obtain

$$d\Pi = L_F d(\Delta t_F)/V(T_0 - \Delta t_F), \qquad (83)$$

where Δt_F is the freezing-point lowering in centigrade degrees and T_0 is the freezing point of the pure solvent on the absolute scale.

In order to integrate we need only express V and L_F as functions of Δt_F. V may be expressed by the equation

$$V = V_0 + a\Delta t_F + b(\Delta t_F)^2 + \ldots\ldots \qquad (84)$$

where V_0 is the molecular volume when $\Delta t_F = 0$ and $\Pi = 0$, and a, b, etc., are constants whose numerical values can be computed from the coefficients of compressibility and thermal expansion of the liquid solvent and from approximate values of Π for different values of Δt_F up to the limit desired. For L_F the first law of thermodynamics gives us the general relation,

$$L_F = L_{F_0} + \Delta C_{P_0}\Delta t_F + {}^1/_2\alpha\Delta t_F^2 + {}^1/_3\beta\Delta t_F^3 + \ldots \qquad (85)$$

In this equation L_{F_0} is the molecular heat of fusion of the pure solvent at its freezing point T_0, ΔC_{P_0} is the attendant *decrease* in the heat capacity of the system and α, β, etc., are constants expressing the dependence of ΔC_p upon the temperature.[23]

Substituting equations (84) and (85) in equation (83) and integrating so as to obtain Π as a series function in Δt_F, we obtain the relation

$$\Pi = \frac{L_{F_0}}{V_0T_0}\left[\Delta t_F + {}^1/_2\left(\frac{V_0 - aT_0}{V_0T_0} - \frac{\Delta C_{p_0}}{L_{F_0}}\right)\Delta t_F^2 + {}^1/_3\left(\frac{(V_0 - aT_0)^2}{V_0^2T_0^2} - \frac{\Delta C_{p_0}(V_0 - aT_0)}{L_{F_0}V_0T_0} + \frac{a - bT_0}{V_0T_0} + \frac{{}^1/_2\alpha}{L_{F_0}}\right)\Delta t_F^3 + {}^1/_4\left(\frac{(V_0 - aT_0)^3}{V_0^3T_0^3} - \frac{\Delta C_{p_0}(V_0 - aT_0)^2}{L_{F_0}V_0^2T_0^2} + \frac{(a - bT)(V_0 - aT)}{V_0^2T_0^2} + \frac{{}^1/_2\alpha}{L_{F_0}V_0T_0} + \frac{(V_0 - aT_0)(a - bT_0)}{V_0^2T_0^2} - \frac{\Delta C_{p_0}(a - bT_0)}{L_{F_0}V_0T_0} + \frac{b}{V_0T_0} - \frac{{}^1/_2\beta}{L_{F_0}}\right)\Delta{}_F^4\right]. \quad (86)$$

This apparently cumbersome equation becomes quite simple when we consider a concrete case, owing to the fact that many of the terms in the parentheses are negligible. Let us consider a water solution, for example, and suppose Δt_F to be known with an accuracy of 0.1 per cent. For this case equation (86) becomes

$$\Pi = 12.06(\Delta t_F - 1.78.10^{-3}\Delta t_F^2 - 2.5\ 10^{-6}\Delta t_F^3)\ \text{atmospheres.} \quad (87)$$

This equation can be used for values of Δt_F as high as 100° without introducing an error of more than a few tenths of one per cent.[24]

Osmotic Pressure and Boiling-point Raising (P = *const.*).—The problem may be stated as follows: How does the osmotic pressure change with the temperature at which the partial vapor pressure of the solvent from the solution is equal to the external pressure upon the solution?

The arrangement of the engine is as follows:

---

[23] In the case of water, for example, we have for its molecular heat capacity at constant pressure, $Cp = Cp_0 + at + bt^2 + \ldots$ and for ice $C'_p = C'_{p_0} + a't + b't^2 + \ldots$ Subtracting the first equation from the second and putting

$$C'_p - Cp = \Delta Cp,\ a' - a = \alpha, \text{ and } b' - b = \beta,$$

we obtain

$$\Delta Cp = \Delta Cp_0 + \alpha t + \beta t^2 + \ldots$$

Combining this with the purely thermodynamic equation,

$$dL_F/dt = -dL_F/d(\Delta t_F) = -\Delta Cp,$$

and integrating, we obtain equation (85).

Strictly speaking, another term should be added to this expression to include the heat of compression of the liquid solvent from P to $P - \Pi$, since the operation of the engine produces liquid solvent at the latter pressure. In most cases this heat effect will be entirely negligible in comparison with the heat of fusion and this assumption is made in equation (85).

[24] The values of the constants for water are: L_{F_0} = 59.309 liter atmospheres, ΔCp_0 = 0.363 liter atmosphere per degree, V_0 = 0.01801 liter, a = 0.000014 liter; α, β, and b are negligible. For examples illustrating the application of equation (87) see Lewis, THIS JOURNAL, 30, 671 (1908).

Chamber **E**: Filled with a solution under the pressure P at its boiling point,[25] T_B. The mol fraction of the solvent is N_A and its partial vapor pressure, acting against piston **A**, is p ($= P$). The pure liquid solvent in cylinder **B** is under the osmotic pressure Π.

Chamber **E′**: Exactly as chamber **E** except that the mol fraction of the solvent is $N_A + dN_A$, the temperature (B. P.) is $T_B + dT_B$ and the osmotic pressure is $\Pi + d\Pi$. The vapor pressure is P.

$d\Pi$ in this instance is given by the expression

$$d\Pi = (\partial\Pi/\partial T)_N(\partial T_B/\partial N_A)_P dN_A + (\partial\Pi/\partial N_A)_T dN_A. \qquad (88)$$

To operate the engine, vaporize one mol of solvent from chamber **E′** by means of piston **AA′** and introduce simultaneously one mol of liquid solvent osmotically by means of piston **BB′**. The reverse process occurs in chamber **E**. The only work involved is that done by piston **BB′**, which is $Vd\Pi$. The heat absorbed at the higher temperature is the molecular heat of vaporization (L) of the pure liquid solvent under the pressure $p - \Pi$ to form vapor at the pressure p. We have therefore by the Second Law,

$$Vd\Pi = LdT_B/T_B, \qquad (89)$$

or

$$(\partial\Pi/\partial T_B) = L/VT_B. \qquad (90)$$

In this equation we can put

$$T_B = T_{B_0} + \Delta t_B$$

and obtain

$$d\Pi = Ld(\Delta t_B)/V(T_{B_0} + \Delta t_B), \qquad (91)$$

where Δt_B is the elevation of the boiling point in centigrade degrees and T_{B_0} is the boiling point of the pure solvent on the absolute scale.

The method of integration to be followed for this equation depends largely on the nature of the solvent, the equation of state of the vapor and the magnitude of T_{B_0} as compared with the critical temperature of the pure solvent. If the vapor of the solvent obeys the gas laws and T_{B_0} is considerably lower than the critical temperature, we could adopt a method of integration identical with that employed for the corresponding freezing point equation and would obtain an integrated expression perfectly analogous to equation (86). Consequently it will not be necessary to consider this case in further detail.

Vapor Pressure and Freezing-point Lowering (P = *const.*).—The problem may be stated as follows: How does the vapor pressure of the solvent from a solution vary with the temperature at which the solution is in equilibrium with the pure solid solvent? Now the vapor pressure from the solution and solid solvent are equal when the two are in equilibrium, consequently this question is the same as inquiring, How does the vapor pressure of the pure solid solvent vary with the temperature? and this relation has already been derived. It is equation (5) which we may write as follows (using T_F in place of T to indicate that we mean the absolute temperature of the freezing point of the solution):

---

[25] Note that the b. p. is here defined as the temperature at which the partial vapor pressure of the solvent is equal to the total pressure on the solution.

$$(\partial p/\partial T_I)_P = L_S/vT_F. \tag{92}$$

In this equation L_S is the molecular heat of sublimation of the pure solid solvent under the pressure P to form saturated vapor at the pressure p. dp is expressed by the equation

$$dp = (\partial p/\partial T)_N(\partial T_F \partial N_A)_P dN_A + (\partial p/\partial N_A)_P dN_A. \tag{93}$$

Let us integrate equation (92) for aqueous solutions. Assuming the perfect gas law for saturated water vapor below 0°, equation (92) may be written:

$$d\ln p = (L_S/R)dT/T^2. \tag{94}$$

Owing to the slight difference between the heat capacities of ice and its vapor, L_S will have such a small temperature coefficient that it may be regarded as constant without much error, even for large values of the freezing point lowering, Δt_F. Integrating equation (94) with this assumption we obtain

$$\ln p_0/p = (L_S/RT_0)\Delta t_F/T. \tag{95}$$

In this equation p is the vapor pressure of the solution at the absolute temperature of its freezing point T.

9. Summary and Conclusion.

1. A simplification of the cyclical process method of Carnot has been described, which reduces the cycle of necessary operations to a single step and allows the desired thermodynamic equation to be written down "by inspection." Not only does this result in an increased clearness and certainty as to the exact significance of the quantities appearing in the equation, but it also insures an entirely rigorous result because it is impossible to introduce into the process any assumption except the two laws of thermodynamics.

2. The use of this simplified process (embodied in what has been called the "Perfect Thermodynamic Engine") as the basis for the construction of a simple but entirely rigorous system of thermodynamic chemistry, is illustrated by applying it to the derivation of a number of fundamental relations.

3. The modified process possesses, to a higher degree, all of the advantages of the ordinary cyclical process with none of its disadvantages. The system of equations which it yields possesses all of the rigor of any of the analytic systems of thermodynamics with none of their abstruse conceptions and intricate, involved and long drawn-out derivations. By means of the perfect thermodynamic engine one can pass in a

single step from the Second Law of thermodynamics directly to the differential equation of the desired relation.

4. In connection with the application of the engine to the subject of chemical equilibrium, the following points have been brought out:

(*a*) Contrary to the statement of T. B. Robertson, the Mass Action Law is not an expression of the condition for equilibrium in a system whose equation of state is $p(v - d) = RT$.

(*b*) The derivation of the Law of the Constancy of the Solubility Product for a solute which dissociates in solution does not involve any assumption regarding the nature of the law which regulates the equilibrium between the undissociated molecules and their products of dissociation. Consequently the theoretical basis for the Solubility Product Law in the case of strong electrolytes is not destroyed by the fact that they do not obey the Mass Action Law, as inferred by Stieglitz.

5. It is shown that many of our equations which contain the van't Hoff i, involve an unnecessary number of assumptions and that each equation can be split up into two simpler equations, one involving only the ions, the other only the unionized molecules. The advantage of so doing is illustrated by a consideration of the experimental data of Noyes and Sammet on the solubility of orthonitrobenzoic acid.

URBANA, ILLINOIS, January 15, 1910.

HETEROGENEOUS EQUILIBRIA BETWEEN AQUEOUS AND METALLIC SOLUTIONS: THE INTERACTION OF MIXED SALT SOLUTIONS AND LIQUID AMALGAMS (FIRST PAPER). A STUDY OF THE REACTION, $KHg_m + Na^{\cdot} \rightleftarrows K^{\cdot} + NaHg_n + (m-n)\,Hg$.

BY GEORGE MCPHAIL SMITH.

Received February 16, 1910.

It has previously been shown[1] that the alkali metals exist, in liquid mercurial solution, in the form of compounds of the general formula $MeHg_n$, containing only one atom of the amalgamated metal to the molecule. It has also been shown that a mixed solution, containing the chlorides of sodium and potassium, reacts readily with either sodium or potassium amalgam, with the rapid establishment of an equilibrium. The same has been found to be the case with sodium and rubidium, and sodium and caesium amalgams, when treated with the corresponding mixed solutions.[2]

The present paper is the outcome of a more detailed study of the first of these reactions. In subsequent investigations the alkali earth and other amalgams will be included.

---

[1] Ueber die relative Beständigkeit bzw. die Konstitution der verdünnten Amalgame der Alkali-bzw. Erdalkalimetalle. G. McP. Smith, *Z. anorg. Chem.*, 58, 381 (1908).

[2] *Loc. cit.*

Experimental Method.[1]—Approximately equimolal liquid sodium and potassium amalgams were prepared, and after filtration through chamois skin on the filter pump, they were at once filled into small sealing bottles, whose necks were then drawn into capillaries and sealed off. At intervals, the measured salt solutions, which had previously stood in the thermostat in stoppered Erlenmeyer flasks, were tared on a balance, and the desired quantities of amalgam were poured into them directly from the opened capillaries.[2] The flasks were then restoppered and put back into the thermostat, and the capillary necks of the sealing bottles were at once re-sealed. The reaction mixtures were agitated for a given time in the thermostat, after which they were taken out, one at a time, and treated as follows:

The aqueous solution was decanted and the amalgam was washed by passing it through a row of 5 beakers, each of which contained about 50 cc. of distilled water; the wash water was decanted each time before the amalgam was poured into the next beaker. In this way each amalgam was washed thoroughly in the course of 1 minute, and the chemical action of the wash water was negligible. The amalgams were finally decomposed with hydrochloric acid, and the extracts were analyzed. The experimental results are given in Table I.[3]

In the reversible reaction,[4]

$$\mathrm{KHg}_m + \mathrm{Na}^{\cdot} \rightleftarrows \mathrm{K}^{\cdot} + \mathrm{NaHg}_n + (m - n)\mathrm{Hg},$$

as carried out in these experiments, free mercury was present in such quantity that its concentration may be taken as constant. We have therefore a heterogeneous equilibrium of the second order, and if $[\mathrm{KHg}_m]$ and $[\mathrm{NaHg}_n]$, $[\mathrm{Na}^{\cdot}]$ and $[\mathrm{K}^{\cdot}]$ represent the relative molal concentrations at equilibrium, then the equilibrium constant,

$$\mathrm{K} = \frac{k_1}{k_2} = \frac{[\mathrm{KHg}_m] \times [\mathrm{Na}^{\cdot}]}{[\mathrm{NaHg}_n] \times [\mathrm{K}^{\cdot}]}.$$

---

[1] The mercury used in the preparation of the amalgams was purified by the ordinary methods, after which it was distilled under reduced pressure in a current of air. The salts were of Kahlbaum's manufacture, and the water employed was obtained by redistilling the distilled water of the laboratory, after having acidified it slightly with sulphuric acid.

[2] In all cases the interaction of the amalgam and the solvent-water was infinitesimal and it will be neglected in what follows.

[3] The five solutions employed in the first 10 experiments contained, respectively, 14.6150 g. NaCl + 9.3200 g. KCl, 7.3075 g. NaCl + 18.6400 g. KCl, 14.6150 g. NaCl + 4.6600 g. KCl, 3.6538 g. NaCl + 18.6400 g. KCl, and 7.3075 g. NaCl + 9.3200 g. KCl; they were made up, one after another, in the same 250 cc. measuring flask.

[4] The values of *m* and *n* are not known for the compounds in solution; they may have several values in the case of the crystalline compounds. For references to the literature, see *loc. cit.*

[1] Samples of the amalgams were taken beforehand from the sealing bottles and analyzed. They gave: Na = 0.29 per cent. and K = 0.45 per cent., respectively.

Experiments 11 and 12 are taken from the paper already cited. In the case of Experiment 13 (which is taken from *Am. Chem. J.*, 37, 517 (1907)), the alcoholic filtrate from the potassium chloroplatinate was evaporated to dryness and the residue tested spectroscopically for lithium, of which not a trace could be detected.

Now, in the case of Experiments 1 and 7, for example,

$$\frac{\dfrac{0.0350}{39.10}[\mathrm{Na}^\cdot]_1}{\dfrac{0.1110}{23.00}[\mathrm{K}^\cdot]_1} = \mathrm{K} = \frac{\dfrac{0.1190}{39.10}[\mathrm{Na}^\cdot]_7}{\dfrac{0.0478}{23.00}[\mathrm{K}^\cdot]_7};$$

whence

$$\frac{]\mathrm{Na}^\cdot]_1}{[\mathrm{K}^\cdot]_1} \Big/ \frac{]\mathrm{Na}^\cdot]_7}{[\mathrm{K}^\cdot]_7} = 7.90.$$

And, starting with 100 cc. of solution and taking into account the changes in concentration during the reaction, we have at equilibrium in the case of these two experiments the molal relations:

$$\frac{(\mathrm{NaCl})_1}{(\mathrm{KCl})_1} \Big/ \frac{(\mathrm{NaCl})_7}{(\mathrm{KCl})_7} = \frac{\dfrac{2.3000 - 0.1110}{2.3000}}{\dfrac{1.9550 + 0.1887}{3.9100}} \Big/ \frac{\dfrac{0.5750 - 0.0478}{2.3000}}{\dfrac{3.9100 + 0.0813}{3.9100}} = 7\ 73.$$

From the approximate equation, 7 90 = 7 73, it follows roughly that

$$\frac{[\mathrm{Na}^\cdot]_1}{[\mathrm{K}^\cdot]_1} : \frac{[\mathrm{Na}^\cdot]_7}{[\mathrm{K}^\cdot]_7} = \frac{(\mathrm{NaCl})_1}{(\mathrm{KCl})_1} : \frac{(\mathrm{NaCl})_7}{(\mathrm{KCl})_7},$$

i. e., in mixed sodium and potassium chloride solutions, the ratios which exist between the relative ion concentrations of sodium and potassium in the different solutions are identical with those which exist between the relative molal concentrations of the two salts in the respective solutions. It is therefore permissible to substitute the latter values in the calculation of the equilibrium constant. The results are given in Table II:[1]

TABLE II.[2]

[1] **In the calculation of the molal concentrations at equilibrium, if sodium amalgam was started with, for example, then the potassium in the resulting amalgam came**

It is interesting to compare with the above the equilibrium constants calculated from previously published results[1] obtained in the action of mixed sodium and rubidium, and sodium and caesium chloride solutions upon sodium and rubidium, and sodium and caesium amalgams, respectively. In these cases the solutions were double molal in respect to each salt in the mixture, so that the concentration changes may be disregarded in calculating the values of the equilibrium constants. The results are given in Table III:

TABLE III.

No.	t°	Time Min	Amalgam at start	At equilibrium $[MeHg_m].[NaHg_n]$.	At start and at equilibrium $[Na^\cdot]$ $[Me^\cdot]$.	$\frac{[MeHg_m] \times [Na^\cdot]}{[NaHg_n] \times [Me^\cdot]}$.	Mean.
1	23	30	Rubidium	27.39 : 72.60	2.0 : 2.0	0.377	0.37
2	23	30	Sodium	26.35 : 73.64	2.0 : 2.0	0.358	
1	24	30	Caesium	32.95 : 67.05	2.0 : 2.0	0.491	0.48
2	24	30	Sodium	32.44 : 67.55	2.0 : 2.0	0.480	

From the foregoing we see that, in the case of the general reaction,

$$NaHg_n + (m-n)Hg + Me^\cdot \rightleftarrows MeHg_m + Na^\cdot,$$

the equilibrium constant is equal to 0.31, 0.37 and 0.48, respectively, when Me stands for K, Rb and Cs, in the order named.

Previous studies of the ionization of salts have led to the conclusion that at any definite concentration salts of the same ionic type have approximately the same degree of ionization. It has also been shown by experimental investigations that the degree of ionization of each salt in such a mixture as KCl + NaCl, in which there is a common ion, is the same as if that salt were alone present with an ion concentration equal to the sum of those of the two separate salts.[2] It therefore follows that, in such a mixed solution,

$$\frac{[Na^\cdot]}{[K^\cdot]} = \frac{\alpha_1(NaCl)}{\alpha_2(KCl)} = \frac{(NaCl)}{(KCl)}.$$

The present investigation offers, through an independent method, a

---

from the solution, and the equivalent amount of sodium must have entered the solution from the amalgam. The chemical action of the solvent water was negligible, as can be seen from the figures given in the last column of Table I.

[2] In regard to experiments 11, 12 and 13, see footnote under Table I. Experiment 13 is evidently unreliable, owing to the low lithium content of the amalgam at the start and to the different temperature. Of the first 10 experiments, the 9th is the least reliable. The source of error is suggested in the last column of Table I, where it is seen that the equivalent potassium content found was greater than that in experiment 7, which was performed 1 day earlier; owing to traces of oxidation in the meantime, the amalgam should have shown a lower potassium content. The mean value of K is not affected, however, if *both* experiments are left in the table.

[1] *Loc. cit.*

striking confirmation of the above conclusions, and, *moreover, it shows that they hold good even in the case of very concentrated solutions.*

URBANA, ILL., February, 1910.

CONCERNING THE CORRECTION OF THE APPARENT WEIGHT OF A SALT TO THE VACUUM STANDARD.

BY THEODORE W RICHARDS AND GREGORY P. BAXTER.

Received February 12, 1910

The tendency to adsorb gases possessed by finely divided carbon is well known, and there can be no question that other substances also possess, although to a much smaller degree, this same tendency. Therefore the possible effect of adsorbed gases upon the weights of the substances entering into very precise determinations, such as those concerning the atomic weights, is worthy of careful consideration. The idea is by no means new, for Marignac nearly seventy years ago investigated several salts with regard to the possibility of such adsorption, and found in most cases very slight, if any, evidence of an appreciable effect.[1] The topic has been recently revived by Guye and Zachariadès in a brief paper, in which are recorded, without details, a number of extraordinary results very different from those of Marignac.[2] The new investigators interpret their figures to mean that the error from this source is in many cases a serious one, rendering illusory the weighing of most powdered salts more accurately than to within one one-hundredth of one per cent.

The experiments of Guye and Zachariadès have been repeated, as far as potassium chloride is concerned, by Alexander Scott, with results confirming Marignac's rather than those of the new investigators. Scott was unable to find any important adsorptive effect, even in finely powdered potassium chloride.[3] His discussion of the matter seems to leave little need of further remark, except for the fact that Guye and Zachariadès specifically mention the recent Harvard investigations upon atomic weights, and their paper might convey to some the impression that these authors believe their results to concern the work at Harvard. It is very easy to show, however, upon the basis of the evidence in the paper, that, whether the interpretation by the two investigators at Geneva is correct or not, in any case their results can have no relation whatsoever to the Harvard work, and do not render necessary appreciable corrections in any of the Harvard investigations.

Guye and Zachariadès weighed successively in air and in vacuum a number of materials which, as they say, "were chosen especially as having served in the determinations of atomic weights in the chemical laboratory of Harvard College." These twenty-six salts were as follows: The nitrates of potassium and silver; the chlorides of potassium, sodium, magnesium, calcium, manganese, nickel, cobalt, iron, cadmium, barium, strontium, and silver; the bromides of potassium, sodium, zinc, barium, strontium, nickel, cobalt, and cadmium; the sulphates of copper and silver; the chlorate of potassium; the oxide of copper. Two of the substances, however—the chlorides of iron and nickel—have never been used as the basis of accurate work at Harvard. The authors conclude that the adsorptive effect "depend de la densité du sel, de l'hygroscopicité, et, à un haut degré des conditions de l'expérience, notamment de la structure physique du sel pesé." Thus, for example, fused potassium chloride in large pieces showed 5 milligrams of adsorption per 100 grams, in crystals 20 milligrams, in powder 32 milligrams. The other twenty-five substances seem to have been investigated in powdered form alone, and only one among them, namely, potassium nitrate, appeared to show as much adsorption as powdered potassium chloride.

[2] Guye and Zachariadès, *Compt. rend.*, 149, 593 (1909).

[3] Alexander Scott, *Proc. Chem. Soc.*, 25, 286 (1909).

Supposing for a moment that the figures just cited really represent adsorbed air, the quantity corresponding to fused material weighed in large pieces would be only enough to affect the atomic weight of potassium calculated from the molecular weight of potassium chloride, by an unimportant quantity, less than 0.004; and potassium chloride was one of the worst of all the substances investigated by Guye and Zachariadès. Hence, even according to their own showing, fused substances in large pieces may be weighed with considerable accuracy.

Now, of the substances in the list used in the Harvard determinations, all except five were fused and weighed in large pieces. This had been done not only because the expulsion of water from a fused salt is more certain than from a solid, but also because the possibility that the powders might adsorb air had been thought of very early in the prosecution of the Harvard researches. For example, in the case of barium bromide, the salt used in Experiments 4 and 13 was fused in a platinum crucible, and yet gave results for the atomic weight of barium and for the content of crystal water essentially identical with those of similar samples which had been merely heated at a high temperature without fusion, being thus in a highly subdivided, effloresced condition.[1] Two of the specimens of barium chloride (those used in Experiments 37 and 38[2]) were fused in a current of hydrochloric acid gas, but gave results for the atomic weight of barium essentially equal within the limit of error of experimentation to those from the unfused effloresced samples. In the later determinations of the atomic weights of other elements, the other substances mentioned by Guye and Zachariadès were all fused and weighed in large pieces except the five already alluded to. Of these five, nickel and cobalt bromides were weighed in the form of crystals of appreciable size, but Guye and Zachariadès found these substances even in a state of powder to show only a slight irregularity. Hence, they could not have been at fault. Copper oxide, another of the five, falls entirely out of consideration, partly because Guye found almost no suspicious effect in this case, and partly because if any air had been adsorbed by copper oxide it would have been determined along with the included nitrogen in the due course of the experiments upon this substance. Copper sulphate was indeed used in a finely powdered condition, but the weight of this substance did not enter into any of the finally accepted values for the atomic weight of copper. Hence the fourth of the unfused substances also falls out of consideration. Cobalt chloride also was used in an effloresced condition, but gave the same results for the atomic weight of cobalt as did the more compact cobalt bromide.

[2] Richards, *Ibid.*, 6, 121, 122 (1894).

Having thus shown that the results of the European experimenters do not at all concern the Harvard determinations, even if some powdered substances really occlude air, we may perhaps repeat a description of two series of experiments carried out within the last two years in the Harvard laboratory with finely divided substances not in the list given by Guye and Zachariadès. In recent experiments iodine pentoxide and powdered silver phosphate have been used as means of obtaining information concerning the atomic weights of iodine and phosphorus respectively Bearing in mind the possibility of this error in question (although at that time the paper of Guye and Zachariadès had not been published), Baxter and Tilley[1] and Baxter and Jones[2] carried out experiments with these two substances respectively. Iodine pentoxide had been made by double efflorescence from iodic acid through the compound $I_2O_5HIO_3$ and therefore must have been an extremely porous material with a surface comparable with that of charcoal. In two experiments with 25.8 grams of material, the air actually displaced by the pentoxide was found to be within about 0.0001 gram of that calculated from the density of the substance.

The description of these experiments is given below:

"Two weighing bottles were constructed with long, very well ground stoppers which terminated in stopcocks through which the tubes could be exhausted. These tubes were very closely of the same weight and of very nearly the same internal capacity. The tubes were first exhausted and compared in weight by substitution. Next they were filled with dry air and again weighed, the weighings being carried out with the stopcocks open." Both steps were then repeated with essentially the same results, the difference in the weight of air contained in the two tubes being found on the average to be 0.00014 gram, the counterpoise being slightly the larger.

---

[1] This Journal, 31, 214 (1909).

[2] *Proc. Amer. Acad.*, 45, 155 (1909). This Journal, 32, 298.

"Into one of the tubes was introduced 25.84 grams of carefully dried iodine pentoxide, and both tubes were completely exhausted. When the tube containing the pentoxide was warmed to about 150° no perceptible quantity of gas was evolved. After the difference in weight of the exhausted tubes had been determined, they were again filled with dry air and weighed, and the process of exhausting the tubes and filling them with air was repeated." The difference between the weight of air admitted to the two tubes now averaged 0.00651 gram, corrected to 19° and 758 mm. Subtracting the difference found for the empty tubes (0.00014 gram), the quantity 0.00637 gram is found as the weight of air displaced by the powder, whereas the value calculated from the density of the solid (4.799[1]) is 0 00649. Thus the amount of air adsorbed by nearly twenty-six grams of the very finely subdivided, effloresced iodine pentoxide was only a trifle more than 0.1 milligram—a quantity scarcely greater than the probable error of experiment. In this case the usual method of calculating the correction to the vacuum standard yields a possible error of only 1 in 200,000.

Similar experiments have been made with *precipitated* and dried silver phosphate by Baxter and Jones with similar results.

"In two experiments, when air was admitted, after exhaustion the counterpoise gained 0.00028 and 0.00021 gram respectively (average 0.00025), more than the tube which was later to contain the silver phosphate. After 22.69 grams of pure dry silver phosphate had been placed in the tube, the tube and its counterpoise were exhausted and the difference in weight determined. When dry air at 25° and 766 mm. was admitted to both the tube containing the silver phosphate and the counterpoise, the counterpoise gained 0.00443 gram more than the tube. Therefore the air displaced by the silver phosphate was 0.00443 — 0.00025 = 0.00418 gram. Since 22.69 grams of silver phosphate of density 6.37[2] have a volume of 3.56 cc., the volume of pure air displaced at 25° and 766 mm. should weigh 0.00425 gram.

"The experiment was then repeated. After the air had been exhausted from the tube and its counterpoise, the tube containing the silver phosphate was heated gently. No gas was evolved. The tube and its counterpoise were then weighed by substitution. When dry air at 24.5° and 767 mm. was admitted to both, the counterpoise gained 0.00445 gram more than the tube containing the silver phosphate. Therefore the air displaced by the silver phosphate was 0.00445 — 0.00025 =

---

[1] Baxter and Tilley, THIS JOURNAL, 31, 213 (1909).

[2] Baxter and Jones, *Proc. Amer. Acad.*, 45, 155 (1909).

0.00420 gram, whereas the weight of air displaced, calculated from the density of the salt, is 0.00426 gram.

"The agreement between the experimental results and those calculated from the density of silver phosphate on the assumption that no adsorption takes place is close enough to show that no significant amount of adsorption occurs."

Furthermore, in many cases dried precipitates of silver halides have been weighed both before and after fusion, and, while in some cases the loss has amounted to 0.01 per cent., owing to moisture retained by the dried salt, in many cases the loss in weight has been very slight indeed, showing that the great diminution in surface is without effect upon the apparent weight. This was especially the case in the recent investigations upon the atomic weights of bromine and lithium, wherein silver bromide and chloride dried for a long time at 180° and 250°, respectively, lost sometimes not more than 1 part in 100,000 on fusion. Even this almost negligible loss was probably due to traces of water imprisoned in the unfused substance.[1]

When with these results we rank the similar results of Scott with potassium chloride, one cannot but believe that many substances at any rate adsorb so little air as not to be greatly affected as to their weights thereby, at least when the solids are weighed in any ordinary state of subdivision.

One other case, that of sublimed ammonium chloride, may receive passing mention. This salt seems to exhibit a slight tendency in the opposite direction, as it gains somewhat more weight in vacuum than corresponds to the calculated correction. According to the concordant results of Marignac, Stas, and Richards and Köthner and Tiede[2] the salt gains 0.00080 gram per gram when the air is exhausted, whereas the best value for the density of transparent ammonium chloride (1.525) corresponds to a gain of 0.000793—a result but very slightly less than the observed value.

Sublimed ammonium chloride is, however, a peculiar substance because, on cooling, it suffers transition into a denser form, causing the crystals to be permeated with pores of molecular fineness. The porosity of the solid renders difficult the determination of its true bulk, upon which depends the correction to the vacuum standard. Some of the interstices would undoubtedly fill with air, while others might not; and none of them would probably fill with a liquid. This would account for Stas's uncertainty about the specific gravity of the salt, and for the various interpretations which have been put upon the results. Hence ammonium chloride, also, is probably not fundamentally abnormal.

[1] Baxter, THIS JOURNAL, 28, 1332 (1906). Richards and Willard, *Ibid.*, 32, 29 (1910).

[2] Marignac, *loc. cit.*; Stas, *Untersuchungen*, Aronstein's translation, p. 56 (1867); Richards, Köthner, and Tiede, THIS JOURNAL, 31, 7 (1909).

The details given in the recent paper by the Geneva experimenters are so meagre that an explanation of their unprecedented results can hardly be attempted. They make no mention of the degree of purity of the salts or the precautions taken in drying them before the experiment. This is, however, a matter of great importance, for the preparation of many of these salts in a pure state, free from water, is a very difficult matter; indeed it is almost impossible to obtain some of them in a powdered form and yet entirely anhydrous. Hence, as they weighed the salts first in air and then in a vacuum, a loss of weight may have been due simply to loss of moisture, as Scott has pointed out in the criticism already quoted. If the salts had been weighed first in vacuum and then in air, the presence of a trace of moisture could have had no effect on the result. Baxter and Tilley, and Baxter and Jones employed this method, as did also Scott.

After the present paper was sent to the press, another paper by the experimenters at Geneva has come to our notice.[1] In it the magnitudes of all the assumed abnormalities have been somewhat changed, and the corrections have apparently been given the opposite sign in every case. Criticism of this unexpected development will not be attempted here; it is enough to say that the arguments brought forward above concerning the Harvard results are not in any wise affected by the changes. No hasty investigation can throw light upon any matter of this kind. The details, both as regard purity of materials and precautions in treatment, must be as thoroughly worked out as in a most careful determination of an atomic weight in order that the work may have any significance.

The contents of this paper may be briefly summarized as follows: First, the possible adsorption of gases by solids had not been overlooked in the Harvard investigations; secondly, even if the conclusions of Guye and Zachariadès hold under their conditions, these conclusions do not essentially affect the determinations of atomic weights conducted in the chemical laboratory of Harvard College; and thirdly, in the light of other careful work carried out, not only in this laboratory but also by Scott, it seems improbable that either of the interpretations by Guye and Zachariadès of their own results is free from fault.

THE ATOMIC WEIGHT OF HYDROGEN.

By Grinnell Jones.

Received February 2, 1910.

In 1908, W. A. Noyes[1] published a table giving the results of all the chemical determinations of the atomic weight of hydrogen, and showed by a careful criticism and comparison that the only data obtained by the chemical methods which need to be considered in selecting the most probable value are those published by Morley[2] in 1895, and by Noyes[3] in 1907.

Noyes states that "densities of gases corrected to the condition of an ideal gas by the method of D. Berthelot may be considered as direct comparisons with oxygen, and molecular and atomic weights calculated from these densities should be included with those determined by chemical methods." But he does not add the results obtained by these physico-chemical methods to his table or discuss their value in selecting the most probable atomic weight of hydrogen.

The object of the present paper is to collect the results which have been obtained by the physico-chemical methods and compare them with the result obtained by the chemical methods. In a few cases the results have been recalculated with the use of the most reliable densities of hydrogen and oxygen at present available, namely, those of Morley. In a few cases other minor corrections have been made and the calculations carried out to one more decimal.

D. Berthelot's[4] "method of limiting densities" for calculating exact molecular weights is based on the deduction from the kinetic theory of gases that all gases approach the ideal gas as the pressure is reduced, and that at infinitesimal pressure, Avogadro's hypothesis is strictly true. This may be expressed in more mathematical language as follows: The limit of the ratio of the densities of two gases as the pressure approaches zero is equal to the ratio of the molecular weights of the gases. Berthelot shows in a very simple manner that these relationships may be expressed by

$$M/M' = (1 - A_0^1)D/(1 - A'^1_0)D',$$

where M and M′ are the molecular weights of the two gases, D and D′ are the densities under normal conditions, and A_0^1 and A'^1_0 are the mean coefficients of the deviation from Boyle's law per atmosphere at

0°, between zero pressure and one atmosphere. This coefficient is defined by the relation

$$d(\mathrm{PV})/\mathrm{PV}d\mathrm{P} = -\mathrm{A},$$

which gives the value of A at any pressure, P, and corresponding volume, V. The negative sign has been inserted simply for convenience, since without this convention A would be negative for all gases except hydrogen and helium, under normal conditions. It has been shown experimentally by Rayleigh[1] and Chappuis,[2] and theoretically by Berthelot,[3] that for the gases formerly called "permanent" the value of A does not vary with the pressure by an appreciable amount below two atmospheres pressure. Therefore, the value A_0^1 can be taken equal to the value of this coefficient as determined experimentally by Leduc and Sacerdote,[4] Rayleigh,[5] Chappuis,[6] Berthelot,[7] and Jacquerod and Scheuer[8] at pressures up to two atmospheres. Although this procedure necessarily involves an extrapolation, the kinetic theory of gases indicates that this extrapolation is a comparatively safe one.

The following table gives the values for A_0^1 and $1-A_0^1$ for hydrogen and oxygen found by different experimenters:

	Hydrogen		Oxygen	
	A_0^1	$1-A_0^1$	A_0^1	$1-A_0^1$
Leduc and Sacerdote	—0 00064	1 00064	0 00076	0 99924
Rayleigh	—0 00053	1 00053	0.00094	0 99906
Chappuis	—0.00058	1 00058	..	.
Jacquerod and Scheuer	—0 00052	1.00052	0.00097	0 99903
Berthelot	—0 00060	1 00060	0.00085	0 99915

The last three experimenters worked at 0°. Rayleigh worked at about 11°, finding at this temperature —0 00052 for hydrogen and +0 00076 for oxygen. He corrected his results to 0° by means of a formula proposed by Berthelot[9] after a careful study of Chappuis' excellent experimental results on this subject. Leduc and Sacerdote found A for oxygen at 16° to be +0.00061, and then corrected this result to 0° by means of a complex empirical formula burdened with numerous empirical constants, obtaining +0.00076. I have made this correction by means of Berthelot's formula and obtained +0.00083. The necessity for applying this temperature correction of course diminishes the reliability of these results. Fortunately, we have compressibility measurements made at 0°. In the case of hydrogen, the value of A varies so little with the temperature that the method of applying the correction is unimportant.

Leduc and Sacerdote did not use their data to calculate atomic weights by the method of limiting densities. When Berthelot first proposed this method, he calculated from these measurements of the compressibility and Leduc's measurements of the densities of hydrogen and oxygen that the atomic weight of hydrogen is 1.0072. There can, however, be little doubt that the density measurements of Morley are the most accurate at present available.[1] Berthelot[2] has recently repeated this calculation, using Morley's densities, and obtained 1.0077 (1.00768). If we correct Leduc and Sacerdote's measurement of the compressibility of oxygen to 0° by Berthelot's method, this result becomes 1.00775, which is probably the best result which can be derived from these measurements.

Similarly, Rayleigh used his own values for the densities and obtained 1.0086, which he admitted to be too high. He did not combine his excellent compressibility measurements with Morley's densities, but when this is done we obtain 1.00775.

Jacquerod and Scheuer used Morley's value for the density, so their result stands, 1.00777.

Berthelot has not yet used his compressibility measurements to calculate atomic weights so far as I have been able to find. His measurements lead to 1.00773.

Unfortunately, Chappuis did not make any experiments with oxygen. His work on hydrogen is very thorough, and is a very valuable confirmation of the calculations made above.

Guye's[3] method for the reduction of the critical constants is based on van der Waals' equation, the constants a and b being calculated from the critical constants. Unfortunately, van der Waals' equation is only an approximation, and for this reason Guye finds it necessary to insert in his formula another term involving the critical pressure and an arbitrary empirical constant. For gases whose critical temperature is above 0°, he finds it necessary to adopt a different and more complex method, involving two empirical constants. Although the method gives results in good agreement with those obtained by chemical methods in most cases, it hardly deserves as serious consideration as the chemical method or Berthelot's method of limiting densities in selecting the most probable value of an atomic weight. Guye,[1] using Morley's values for the densities, and Dewar's values for the critical constants of hydrogen ($Tc = 32$, $Pc = 19.4$), and Olszewski's values for the critical constants of oxygen, has calculated the atomic weight of hydrogen to be 1 00765. If we substitute Olszewski's[2] recent data for the critical constants of hydrogen ($Tc = 32°$, $Pc = 13.4$ to 15), we obtain 1.0078.

---

[1] See Guye, THIS JOURNAL, 30, 143 (1908).

[2] Berthelot, *Compt. rend.*, 144, 78 (1907).

[3] *J. chim. phys.*, 3, 321 (1905), and many other articles.

Berthelot[3] has criticized Guye's method on theoretical and mathematical grounds and proposed a method of his own for the calculation of the correction to the ratio of the densities by the help of the critical constants. This method is based upon a modified form of van der Waals' equation, which Berthelot[4] proposed after a careful consideration of Chappuis' wonderful experimental work on hydrogen, nitrogen, and carbon dioxide under conditions not very far removed from normal. Berthelot calls this method the method of "indirect limiting density," but it would seem to be more appropriate to call it Berthelot's method of "critical constants," since the critical constants are used instead of the compressibility as in Berthelot's "direct limiting density" method. Berthelot, using the critical constants of Wroblewski, which have recently been confirmed by Olszewski, has calculated the atomic weight of hydrogen to be 1.0076. The critical pressure of hydrogen is not known with sufficient accuracy to determine the fourth decimal place by this method, even if we assume that the formula is exact.

Leduc,[5] using his method of molecular volumes, calculates the correction which must be applied to the ratio of the densities of gases by means of a very complex formula containing six empirical constants. Although a result obtained in this way has very little value as proof of an exact atomic weight, Leduc's result is included for the sake of completeness and to show that its evidence does not conflict. Leduc, using his own values for the densities, obtains $H = 1.0073$. If, however, we combine Morley's values for densities with Leduc's correcting factor, we obtain $H = 1.00765$.

In the following table the final corrected results are collected. The name before each number does not necessarily mean that the number can be found in the literature in an article published by the given author. In the case of the method of limiting densities, the numbers have been calculated by Berthelot's method from the experimental data on compressibility, found by each authority named. In the case of the other physico-chemical methods, the name indicates the method of calculation used. All the results are derived from Morley's values for the densities (except, of course, the results of the chemical methods which are independent of these results):

THE ATOMIC WEIGHT OF HYDROGEN.

Chemical methods:	
Morley	1.00762
Noyes	1.00787
Mean of chemical methods	1.00775
Method of limiting density:	
Leduc and Sacerdote	1.00775
Rayleigh	1.00775
Jacquerod and Scheuer	1.00777
Berthelot	1.00773
Mean	1.00775
Method of critical constants:	
Guye (Dewar)	1.00765
Guye (Olszewski)	1.0078
Berthelot (Wroblewski, Olszewski)	1.0076
Method of molecular volumes:	
Leduc	1.00765

All of the physico-chemical results fall within the limits of the best chemical data. The wonderful agreement of the results obtained by the method of limiting density shows that the compressibility data are probably very accurate, and that the largest source of error in these results is probably Morley's density of hydrogen.

The conclusion drawn by Noyes from the chemical methods that 1.00775 is the most probable value for the atomic weight of hydrogen, is confirmed in a very striking manner by the method of limiting densities, which, as has been pointed out, is the most reliable of the physico-chemical methods.

URBANA, ILL., February 2, 1910

THULIUM.

(PRELIMINARY ANNOUNCEMENT.)

BY C. JAMES.

Received February 26, 1910.

The writer has obtained about 250 grams of the bromate of Cleve's thulium by the continued fractionation of the rare earth bromates more soluble than erbium.

This earth, discovered in 1879, has hitherto never been obtained in a pure condition. It is very rare, and comparatively large amounts of the ytterbiums are obtained during its preparation.

To obtain this quantity of material about 200 kilos of euxenite, ytterspar, gadolinite, fergusonite and yttrotitanite were employed; and in addition the yttrium earths derived from large quantities of monazite, supplied by the Welsbach Light Company through the courtesy of Dr. H. S. Miner, to whom many thanks are due.

Thulium bromate is more soluble than erbium bromate, but less soluble than the corresponding compound of ytterbium.

Thulium salts are of a pale bluish green color, best seen in artificial light. However, this tint is very readily destroyed by minute amounts of erbium, the solution becoming first yellowish green, then yellow, colorless, and lastly pink as the erbium content increases.

The material is still undergoing fractionation so as to make sure of the non-complexity of this element.

In addition to the above, it may be as well to state that the more soluble portions are being carefully studied, since the most soluble fractions are colored pale yellowish green when in solution while the intermediate fractions between these and thulium are colorless.

It is expected that early in May the determination of the atomic weight will have been completed and a study of the compounds commenced. All these fractions are being examined by means of a quartz spectrograph and Sir William Crookes has kindly offered to investigate the spark spectra of thulium and erbium with the unequaled instruments at his disposal. This latter element has also been obtained in a high state of purity.

NEW HAMPSHIRE COLLEGE, DURHAM, N. H.,

THE MARSH TEST AND EXCESS POTENTIAL.

(FIRST PAPER.[1])

THE QUANTITATIVE DETERMINATION OF ARSENIC.

BY W. D. HARKINS.

Received May 14. 1909.

Introductory.

The most widely used method for the determination of small quantities of arsenic is the separation as arsine suggested by Marsh,[2] together with the decomposition of this gas in a heated glass tube as recommended by Liebig.[3] An excellent review of the history of the development of this method has been given by Lockemann.[4]

---

[1] Presented at the New York meeting of the American Chemical Society, December 28, 1906, and in part at the December, 1905, meeting of the Stanford Chemical Society.

[2] *Ann.*, 23, 207 (1837).

[3] *Ibid.*, p. 217.

[4] *Z. angew. Chem.*, 18, 416 (1905).

In the year 1902 the writer attempted to utilize the Marsh method for the direct determination of the arsenic contained in the acid extracts from soils, but found that the amounts of arsenic recovered were entirely too small. This was explained by the work of Parsons and Stewart[1] and other investigators[2] as due to the retentive effect of the iron present in the solution. According to Headden and Sadler[3] a successful determination by this method can be made only in the absence of iron, copper, platinum and their salts.

In spite of the exidence cited above, and that of other observers,[4] A. H. Allen[5] recommends that zinc should always contain a certain amount of iron to insure a regular evolution of hydrogen, and Gautier[6] advises that platinic chloride be added in order to make the zinc active. Even in what he claims to be his most delicate method,[7] he precipitates the arsenic together with ferric hydroxide and adds the solution of this precipitate, containing about 0 1 gram of iron, directly to the Marsh generator.

Retention of Arsenic by Iron and Other Metals.

In view of these facts it was thought advisable to repeat a portion of the work of Parsons and Stewart. The experiments confirmed their work in every respect, showing that approximately the same percentages of arsenic were held back by the iron as those given in their paper. The results obtained, together with a few of the data given by Parsons and Stewart, are appended in Table I:

TABLE I – RETENTION OF ARSENIC BY IRON.

In addition to these results it was found that mercury, platinum, silver, palladium, nickel, cobalt, and their salts were injurious in their action, particularly mercury,[1] and that copper is injurious when added in large amounts as copper sulphate to the solution. The following table gives the results of four experiments upon copper.

TABLE II

Grams Zn	Grams Cu	Time Hrs	Arsenic Found Mg	Arsenic Added Mg
35	0.037	6	1.88	1.88
35	0.184	6	1.80	1.88
35	0.368	6	1.79	1.88
35	7.000	6	0.22	1.88

The addition of tin, bismuth, cadmium, lead, or their salts to the generator did not cause the retention of any arsenic, except in cases where their addition diminished the rapidity with which the zinc was dissolved.

The Separation of Arsenic from Iron by Heating the Marsh Generator.

It was observed early in the course of the experiments upon the retention of arsenic by iron, that even after the arsenic had almost stopped depositing in the tube, a sudden increase in the rapidity of the evolution of hydrogen would cause a considerable evolution of arsine. It was found impossible to obtain a quantitative separation by merely increasing the rate of evolution of the hydrogen, but, when the generator was heated to 100° in a water bath, excellent results were obtained. The apparatus is shown in Fig. 1.

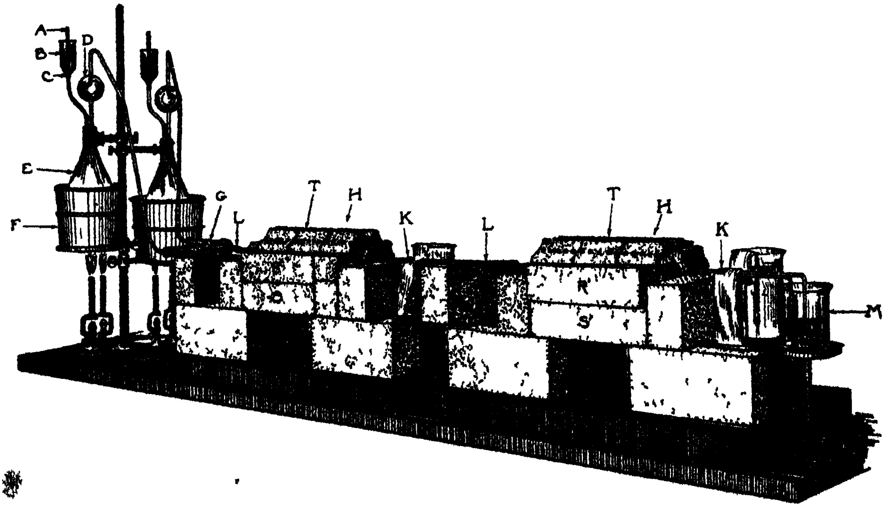

Fig. 1.—Apparatus for the determination of arsenic.

---

[1] Wm. Thompson, *Chem. News*, 85, 173 (1901) and 86, 179 (1902). The action of the mercury is very different from that of the other injurious metals, since it lessens the rapidity of the solution of the zinc, while the other metals increase its rate of solu-

At *A* is connected an apparatus giving arsenic-free hydrogen, which is passed through the tube *A C* into the flask *E*, until the air in the apparatus is completely displaced. Then, by turning *A*, acid may be dropped into the flask upon the zinc. The arsine and hydrogen pass through a Kjeldahl bulb, *D*, and a drying tube of calcium chloride, *G*, into a Jena hard-glass tube which lies in the fire-brick furnace *R S*. A second tube and furnace are always used to test the completeness of the decomposition of the arsine. The tubes are cooled at *K* by a strip of wet filter paper, or better by water flowing through a metal trough. Except where large quantities were determined, the glass tube was four millimeters in internal diameter, but drawn out to a smaller diameter where the arsenic was to be deposited. For all amounts greater than one-half milligram, the tube was enlarged to a bulb at *K*. The tube was finally cut at *a* and *c* (Fig. 2) and wiped by a slightly moist cloth. The tube was then left in the balance case for a considerable time and weighed by substitution against a tube of the same size and shape and made from the same glass. The arsenic was then dissolved in nitric acid and the tube washed with distilled water, dried in air, and finally weighed exactly as before on a balance sensitive to 0.005 mg. To avoid errors in a weighing care must be taken to deposit the arsenic in as small a tube as possible. Most of the weighings were made at a high altitude, where the air is light and very dry. The tubes were handled by forceps with flexible platinum tips, and by platinum wires.

Fig. 2.

For each analysis about forty grams of arsenic-free zinc were used. The determination was begun by dropping a cold hydrochloric acid solution of the arsenic at such a rate that all of the arsenic was added during a period of one-half hour. Then the solution was heated gradually by boiling, and when the action had subsided somewhat more hydrochloric acid (sp. gr. 1.1) was added,[1] 100 to 150 cc. of acid in all. Finally 25

[1] All of the methods for the purification of hydrochloric acid described in chemical literature were tried, and in addition some others which seemed to give promise of success. The only method which always gave perfectly arsenic-free hydrochloric acid was a modification of that described by Otto ("Ausmittelung der Gifte," p. 159). Either mercuric chloride or copper sulphate was added to hydrochloric acid of a density of 1.10, in the proportion of ten to twenty grams to six liters of acid. Hydrogen sulphide was then passed until the salts were completely precipitated as sulphides, the bottle stoppered, and the solution allowed to stand for four or five days. At the end of this time it was filtered and the filtrate distilled, the first quarter of the distillate being rejected.

cc. of concentrated sulphuric acid mixed with 25 cc. of water were added to the generator. At once, when all the zinc was dissolved, the burners of the fire-brick furnaces were extinguished, the tile lifted from the furnaces, and the tubes cooled as quickly as possible. If this is not done, air will draw back into the apparatus and water vapor be formed and condensed, thus spoiling the determination. In cases where time is an object, the generator should be heated from the beginning.

After a series of preliminary experiments the results given in Table III were obtained:

TABLE III.—EFFECT OF HEAT UPON THE RETENTION OF ARSENIC BY IRON.

Wt. zinc. Grams.	Time cold. Hours.	Iron added Gram.	Time 100°. Hours.	Arsenic found. Milligrams.	Arsenic taken. Milligrams.
35	8	0.0	0.0	1.87	1.88
30	5	0.0	0.0	1.84	1.88
30	5	0.075	1.5	1.85	1.88
50	1	0.400	6.5	1.82	1.88
30	3.5	0.300	4.5	1.87	1.88
35	4.0	0.160	2.5	1.87	1.88
40	1.0	0.160	3.0	1.86	1.88
40	0.5	0.400	2.5	1.86	1.88
40	0.5	0.400	4.0	1.89	1.88
40	0.5	0.400	4.0	1.90	1.88
40		0.400	2.0	1.80	1.88
40		0.400	2.0	3.76	3.76
40		1.000	2.0	3.70	3.76

A comparison of these results with those given in Table I shows that heating the generator practically doubles the amount of arsenic reduced. It is evident that the directions which usually accompany the description of the Marsh test, namely that the generator be kept cold, are certainly erroneous and just the opposite of the best procedure. The directions should say that the concentration of the sulphuric acid present should be kept small near the beginning of the determination. For this reason hydrochloric acid is the better acid to use at first. The addition of moderately concentrated (1 : 1) sulphuric acid toward the end of the test improves the results, and the acid does not prove injurious by a resulting reduction.

In several cases, where the arsenic was deposited with extreme rapidity, a part of the mirror was a dark brick-red. This was not due to selenium, since the latter metal was not present. It is possible that this red substance was an allotropic modification of arsenic. In these experiments a white crystalline deposit was often obtained between the gas flame and the arsenic mirror. It is much less volatile than the arsenic, and can easily be separated from the latter by cutting the tube at the proper point. In appearance it is somewhat similar to that obtained when aluminium is used in the place of zinc in the generating flask. These deposits will be collected until a sufficient amount is obtained for the determination of the composition of the crystals.

The Separation of Arsenic by the Addition of Salts to the Generator.

The purest zinc which can be purchased dissolves in pure sulphuric acid with extreme slowness. If the salt of a metal which lies lower in the electromotive series is added to the acid it is found that in almost all cases the metal precipitates upon the zinc, but in such a way as to leave a part of the zinc surface in contact with the solution. If the metal thus precipitated has a lower excess potential than the zinc, which is the case with all of the metals considered in this paper with the exception of mercury, it would be expected that hydrogen would be liberated more easily from the surface of the second metal. In such cases we find that the zinc dissolves more rapidly than before, except that when salts of iron are added without vigorous stirring a considerable time often elapses before its effect is perceptible.

We may assume that the mechanism of solution of the zinc is now as follows: positively charged zinc ions pass from the surface of the zinc into the solution, and positive hydrogen ions are deposited upon the surface of the other metal, which for convenience we may consider as platinum. Gaseous hydrogen soon escapes from the surface of the platinum, and the mechanism of the reaction is the same as though the zinc and the platinum were connected by a wire, lying outside the solution. The system is a galvanic cell in which the zinc is the negative pole. So far as the platinum is concerned, however, the conditions are practically the same as if it were the cathode in an electrolytic cell containing sulphuric acid as an electrolyte. With such a system the reduction may take place either at the surface of the zinc or of the platinum electrode. If at the latter surface only, we have a case of cathodic reduction similar to that described by Tafel[1] or by Haber,[2] except that the depolarizer is itself a weak electrolyte in the case under investigation.[3] If we assume that the reduction takes place upon the surface of the cathodic metal, the reducing power should be related in some way to the value of the cathode potential. This potential depends upon the current density, the concentration of the oxide of arsenic, and the value of the excess potential for the particular metal. The value of the cathode potential (E) is given by the equation of Haber[4] for the case where no free hydrogen is liberated,

---

[1] *Z. physik. Chem.*, 34, 197 (1900).

[2] *Ibid.*, 32, 193 and 271 (1901); 47, 257 (1904).

[3] Luther and Schilow, *Z. physik. Chem.*, 46, 777 (1900). This, of course, makes *possible* the direct electrolytic separation of arsenic, provided that the conditions are favorable. That arsenic is precipitated as a metal when the reducing action in the generator is small is well known (Parsons and Stewart, *loc. cit.*).

[4] *Z. physik. Chem.*, 47, 259 (1904).

$$E = x(\mathrm{RT}/n \ln I/C_{\mathrm{M}}C_{\mathrm{H}^{\cdot}} - \mathrm{const.}),$$

where I is the current density; C_M, the concentration of the substance to be reduced; $C_{H^{\cdot}}$, the concentration of the hydrogen ion; x is a number greater than one, whose value depends upon the value of the excess potential for the metal, and the subtractive constant represents the catalytic influence of the cathode metal upon the reduction in question.

From a theoretical standpoint, the simplest case for investigation would have been the reduction of the oxide of arsenic in an electrolytic cell,[1] with a high concentration of arsenic, vigorous stirring, and a relatively low current density. However, since the work was undertaken at the beginning in order to increase the accuracy of the quantitative determination of small (but still weighable) amounts of arsenic by the ordinary Marsh method, the most favorable conditions for the proof of the theory were not chosen, but instead a much more complicated system was used in which the concentration of the oxide of arsenic was low, and the current density large. Of the factors in the determination of the potential at which the hydrogen is liberated, the excess potential, the current density, and the catalytic action of the metal may be varied; but since nothing is known in regard to catalyzers for this reaction it was decided to work by choosing the first two factors properly and neglecting the last.

That arsenious oxide could be more readily reduced to arsine in the Marsh generator if the salt of a metal other than zinc was added, was suggested in 1893 by Thiele.[2] In trying to determine large amounts of arsenic he found that he could not get a complete reduction of the arsenic unless stannous chloride was added toward the close. Preliminary experiments made upon the basis of these suggestions showed that arsenic can be quantitatively separated from iron or *other injurious metals* by the addition to the solution of salts of bismuth, tin, lead, and cadmium.[3]

In these experiments dilute sulphuric acid was used, of the concentrations advised by Chittenden and Donaldson, though in some instances hydrochloric acid was added to hasten the solution of the zinc. When salts of lead were added to the generator, hydrochloric acid was always used, since in this case sulphuric acid acts slowly upon the zinc. Forty grams of zinc were used for each determination, and enough of the stannous chloride or other salt added to make the zinc active. The arsenical solution, together with the iron and more of the stannous chloride, was then added drop by drop. By the continuous addition of more acid and stannous chloride the action was kept as rapid as was possible without the loss of arsenic from the heated glass tube, until the zinc was almost all dissolved. In this way it was found that weighable quantities of arsenic could be separated quantitatively from as much as 0.300 gram of iron. It is probable that the separation can be made also from a larger amount, but this was not investigated. It should be remembered that, according to the work of Parsons and Stewart, as little as 0.060 gram of iron is sufficient to prevent the reduction of thirty-one per cent. of the arsenic present.

---

[1] Thus eliminating any possible reduction by the zinc.

29	0.300 "	2.0 "	1.86	1.82
30	0.155 "	No salt	1.86	(0.99)

Numbers inclosed in parentheses ( ) show the retentive effect of salts of iron or platinum, when the salt of another metal is not added.

[1] In experiment 17 the amount of arsenic recovered was slightly lower than it should have been. Since but 40 grams of zinc were used, in experiments 18 and 19 this amount was increased to 100 grams, and the size of the flask to one liter. Under these conditions no difficulty was experienced in the determination of more than a tenth of a gram of metallic arsenic, so this method could be used for the separation of arsenic from iron in ores containing arsenic.

It was found possible to make this separation with either arsenious or arsenic acid when the iron was added either in the ferrous or the ferric state, but the results given above were obtained in experiments where arsenious oxide alone was used.

In the preliminary experiments cadmium salts did not give such good results as when salts of tin were added. This seems due, in part, to the fact that the evolution of hydrogen was much less rapid in the former case. Bismuth salts are less easily purified, and lead salts produce an insoluble sulphate when sulphuric acid is used. For these reasons, most of the experiments were made with stannous chloride. The salts used were purified from arsenic, and all of the other reagents were also purified in cases where arsenic was present.

Good results were obtained by the electrolytic method in the absence of iron when as much as two milligrams of arsenic were present, but the addition of stannous chloride has not produced the same favorable result in the presence of iron as is obtained when the ordinary Marsh generator is used. When zinc electrodes are used in the presence of stannous salts the electrodes dissolve rapidly, so that the conditions are almost the same as those in the ordinary Marsh test.

It was considered possible that a part of the great retentive action of iron salts might be due to a chemical action between the iron salts and the arsine. To test this, the arsine produced in experiments such as those given in Table IV was passed through concentrated solutions of iron salts, with the result that no arsine was absorbed. This, of course, does not prove that compounds are not formed at the surface of the zinc in the generator.

In order to see if there is a connection between the excess potential of the metals and the reducing action of the hydrogen liberated from these metals in the Marsh generator, it was essential to determine a number of excess potentials previously undetermined. These determinations are now in progress, and nearly all of the common and rare metals which can be obtained in a suitable form have been procured for use in this work. The greatest difficulty experienced has been that of keeping the surface of the metals in a proper condition, and at the same time to eliminate the last traces of oxygen from the apparatus.[1]

Approximate determinations of the excess potential were first made by the method of Caspari. The results of these determinations, although made by a method which is only approximate in its results, are of some value in connection with the data presented. It is hoped that more accurate numbers can be presented in the second paper. It is universally recognized that the value of the excess potential of a metal depends to such an extent upon its surface condition and its previous condition as an electrode that it is impossible to obtain concordant values.

TABLE V.—THE EXCESS POTENTIAL OF THE METALS IN VOLTS AS DETERMINED BY THE APPROXIMATE METHOD OF CASPARI.

Metal.	Excess potential in volts Caspari.	New determination	Tafel[1]
Mercury	0.78	0.74	1.30
Zinc	0.70	0.71	. . .
Lead polished	0.64	0.62	1.30
Lead rough	. .	. .	1.23
Tin	0.53	0.55	1.15
Cadmium	0.48	. . .	1.22
Arsenic		0.39	. .
Bismuth		0.38	1.00
Copper	0.23	0.25	0.79
Cobalt	.	0.22	. .
Nickel	0.21	0.15	0.74
Silver	0.15	0.13	0.93?
Gold	0.02	. . .	0.95
Iron	0.07	. . .	. . . .
Platinum	0.09	0.07	. . . .
Platinum black	0.005	0.002	0.07
Palladium	0.48	0.02	. .
Palladium black	. .	0.002	. .

Temperature = 20° C.

A study was made of the variation of the excess potentials of bismuth and copper with the current density. The curves of excess potential follow in general the equation

$$E = A + B \log I,$$

in which A and B are constants. From the measurements of Caspari and of Tafel[2] it would seem that the values of B for silver and gold are greater than for nickel and platinum. This shows that it is unsafe to draw too definite conclusions as to the relationship between excess potential and the reducing action of hydrogen in the Marsh generator, until the curves of the variation of excess potential with the current density are more definitely determined. That other factors than current density influence the excess potential is shown by the results of Tafel upon the potential of a silver electrode. When the silver cathode was separated from the anode by a porous cell, the potential value for 0.125 ampere per sq. cm. and 2 N sulphuric acid was about 1.5 volts, while, when there was no separating wall between the anode and the cathode, the potential soon fell to 1.15 volts.

---

[1] *Z. physik. Chem.*, 50, 712 (1904). The values given are for a current density of 0.1 ampere per square centimeter.

[2] *Z. physik. Chem.*, 50, 712 (1905).

It will be seen by referring to the values for the excess potential of the metals given in Table V, that those metals which were found favorable to the reduction of the oxides of arsenic to arsine are metals of high excess potential, while those which proved unfavorable were metals of low excess potential.

The one seeming exception to this rule, in the case where a salt of mercury was added, was due to the effect of the mercury in decreasing the speed of the solution of the zinc, just as would be expected when the zinc becomes coated with an amalgam whose excess potential is as great or greater than that of the zinc itself.

That the rapidity of the reduction and its completeness depended also upon the speed with which the hydrogen was evolved, and therefore upon the current density, was proved by varying the speed of solution of the zinc and weighing the arsenic deposited for a certain time interval.

The system used was so complicated that the experiments gave little light as to the catalytic effect of the different metals upon the reduction. That the electrolytic method is more favorable for the investigation of this problem is obvious. It is probable that the reduction of arsenious oxide to arsine takes place in two or more stages, and it is possible that an intermediate reduction product other than arsenic may be found.

When the iron was alloyed with the zinc used in the generator, it had the same injurious effect as if it were added to the solution as a salt,[1] and the addition of stannous chloride proved favorable as before.

If we consider the system previously discussed, that of platinum deposited upon zinc, it is to be expected that, on account of the lower excess potential of the platinum, the hydrogen given off will have a low reducing power. That the amount of arsenic reduced to arsine is less than that added to the generator was proved by a number of experiments, only one of which is listed in Table IV (Experiment 26). If a salt of tin is now added, the tin precipitates upon the platinum (and upon the zinc as well) and covers it in such a way that a new surface is substituted. If this new surface has the same excess potential as tin, the reduction should become more rapid than before. That this is the case has been proved in a number of instances.

When a salt of iron is dissolved in the solution the case is more complex, since practically all of the iron remains in solution, together with a part of the arsenic. Whatever may be the cause of the tendency of iron to prevent the reduction, it is probable that the beneficial action of the tin added is due to an increase of potential at the surface from which hydrogen is liberated.

The separation of arsenic from iron is extremely important in work where only traces of arsenic are present, for almost all substances which contain arsenic also contain small amounts of iron, and in no case is the zinc used free from iron. For this reason, whenever the Marsh method is used, the conditions should be such as are favorable to the separation of the arsenic from the iron which is always present.

---

[1] Parsons and Stewart, *Loc. cit.*

The results of this work should not be understood to mean that the excess potential alone is the determining factor in the reduction, but only that it is one factor. A study of the electrolytic reduction of arsenic and arsenious acids will undoubtedly prove that certain metals of lower excess potential are more efficient cathodes for purposes of reduction than certain other metals of higher excess potential.

It is interesting to note that arsenic itself is a metal of moderately high excess potential, so that, if any arsenic were precipitated upon the zinc, the reducing action of the system would not be materially lessened. The addition of a solution of arsenic to the Marsh generator makes the zinc "active" without the addition of the salt of any other metal.

The fact that the value of the excess potential of the metal added to the generator has an influence upon the reduction, proves that at least one step in the reduction takes place at the surface of this metal, and that at least this part of the reduction is due, therefore, to the hydrogen and not to the zinc.

Summary.

1. The addition of salts of tin, cadmium, lead, or bismuth to the liquid in the Marsh generator makes the zinc "active" without the decrease in reducing power which comes from the platinum or iron commonly added as salts, or as alloys with the zinc.

2. Arsenic may be separated quantitatively from iron and determined in one process by either heating the generator or by adding a salt of one of the metals named above.

3. So far as has been investigated, metals of low excess potential hinder the reduction in the Marsh generator, while metals of high excess potential do not have any injurious action. However, it is not claimed that this will be a perfectly general relation, since the variation of other factors will undoubtedly be great enough to cause exceptions to the general rule.

4. The speed of the reduction of an oxide of arsenic increases with the rapidity of evolution of hydrogen, provided that the latter effect is not due to the addition of a metal of low excess potential; or the speed of reduction depends upon the current density. This is to be expected, since the current density is one factor in determining the electrode potential.

5. The determination of arsenic is made more accurate by the use of a special form of furnace for heating the glass tubes in which the arsenic is decomposed.

6. Since as much as 0.1 gram of metallic arsenic may be separated

from iron and determined quantitatively, this method is applicable to the analysis of ores and other substances containing large amounts of arsenic.

7. The method may also be used for amounts of arsenic as small as 0.001 milligram, but the apparatus must be made much smaller than that described.

ELECTROLYTIC DETERMINATION OF ZINC.

BY ELLWOOD B SPEAR, EDWARD E WELLS AND BRAINERD DYER.

Received February 14, 1910.

Many methods have been proposed for the electroanalysis of zinc,[1] but unfortunately other experimenters have not always been able to get the degree of accuracy that the advocates of a particular method claim it is capable of giving. One of us, while doing some electrolytic determinations of zinc, invariably got high results by several methods. About the same time a paper appeared by Price[2] in which he stated that the values obtained by all electrolytic methods for zinc are too high. The object of this and the succeeding article was to determine, if possible, the magnitude and cause of the error.

The following methods were investigated:

1. The sodium acetate method.
2. The potassium oxalate method.
3. The sodium, or potassium hydroxide method.

The endeavor was made to follow the directions given in the literature as closely as possible while testing each method. Unfortunately, the instructions are sometimes incomplete, especially with regard to the factors, current density, current in amperes and area of cathode surface. It is not sufficient to give the current density, or the current in amperes alone. Two of these factors should be given from which the third can be calculated.

Over 200 determinations with the above methods have been made and it has been found that when the zinc was completely precipitated the results were invariably too high.

The effect of varying the following factors was also investigated:

1. Nature and concentration of the electrolyte.
2. Form and material of the cathode.
3. Current density.

4. Temperature.

The following tables contain a few results that are typical of those obtained during this investigation:

Preparation of the Solution.—The zinc solutions were made by dissolving a weighed amount of pure zinc (0.2–0.4 gram) in 4 cc. of nitric acid (1.2) and evaporating almost to dryness, after the addition of about 2 cc. of concentrated sulphuric acid. The zinc sulphate was dissolved in water, the electrolyte in question added and the solution made up to the necessary volume. At the completion of the electrolysis zinc was always tested for in the remaining liquid by the methods given in the last part of this article.

In the following tables under "Kind of electrode" A is a rotating (500 revolutions to the min.) copper gauze. B is a platinum dish plated with copper. C is a platinum crucible on which the zinc was directly precipitated. D was a stationary platinum plate covered with a light deposit of copper. E was a stationary, silver gauze.

When the deposits are good the error is very much smaller than when they are loose- and coarse-grained. One of these bad deposits was obtained and analyzed in the following manner: C. P. zinc was made the anode and a platinum plate the cathode in a sodium hydroxide solution. The current was made high enough to cause the zinc to tree on the cathode and fall off. As fast as this occurred the zinc was removed, washed with water and dried at 150°. About 3 grams were prepared in this manner. On further heating at 150° for 4 hours only a very slight increase in weight (0.6 mg.) took place. Two samples of 1 gram each were analyzed by the ammonium phosphate method and one by the carbonate[2] method. The per cent. of zinc obtained was 88.38, 88.13, 88.17, respectively. The causes for this error are discussed in the following article.

The Detection of Small Quantities of Zinc.—In order to determine when all the zinc is deposited it is necessary to have a convenient and accurate test. The delicacy of the tests for zinc is greatly reduced by the presence of large amounts of the salts of organic acids,[1] *e. g.*, oxalates, where complex zinc salts may be formed, and doubtless many investigators have been misled because of the failure to take cognizance of this fact. Some of these tests have been investigated as follows:

A dilute solution of zinc sulphate (1 cc. contained 1 mg. Zn) was made by dissolving pure zinc in nitric acid, adding sulphuric acid and evaporating just to dryness. Solutions similar to those used in the electrolysis in contents and volume were then made and the delicacy determined by finding the least quantity of zinc that would give a precipitate with the reagent in question. The results are summed up in the following paragraphs in which the concentrations of zinc are given in milligrams per liter.

[1] Talbot, "Quantitative Chemical Analysis," page 64. Dakin, *Z. anal. Chem.*, 39, 273 (1900).

[2] Treadwell and Hall, "Analytical Chemistry," Vol. 2, page 117 (1904).

Freshly prepared ammonium sulphide is not a good testing reagent for zinc at room temperatures. Ten mg. sometimes produces no turbidity. The delicacy is improved somewhat by raising the temperature to 50–60°. The objection to polysulphide is the precipitation of sulphur.

Hydrogen sulphide is a very satisfactory reagent. In a neutral solution of zinc sulphate 1 mg. of zinc may be detected at 50–70°. The limit at the same temperature is about 4 mg. if 100 cc. 0.90 ammonia are added. At 10°, with 40 cc. of 0.90 ammonia present, 10 mg. of zinc will not produce any turbidity for several minutes. Hydrogen sulphide, with or without ammonia, is not a delicate test for zinc when large amounts of potassium oxalate are present.

Potassium ferrocyanide is very satisfactory at a temperature between 50 and 70°. The solution should be made acid with 10–15 cc. of sulphuric acid (1.84) and potassium ferrocyanide added until the concentration is about 25 grams per liter. Under these conditions 0.5 mg. of zinc will produce a turbidity even in the presence of large amounts of the salts of organic acids.

ON THE CAUSES OF THE HIGH RESULTS IN THE ELECTROLYTIC DETERMINATION OF ZINC.

BY ELLWOOD B. SPEAR.

Received February 14, 1910.

It has been shown in the previous article that the electrolytic determination of zinc by several methods is attended by high results. The cause must then be due to the presence of some foreign substance in the deposit such as:

1. Enclosure of liquid.
2. Salt precipitated with the zinc.
3. Hydrogen adsorbed or deposited as hydride.
4. Metal deposited with the zinc.
5. Zinc oxide or hydroxide deposited with the zinc.

The first part of this article consists of a detailed consideration of the above-named possibilities and the conclusion is finally reached that the formation of zinc oxide, or hydroxide, is the real cause of the high results. The second part deals with theoretical considerations.

The method of preparation of the solutions to be electrolyzed and the experimental conditions during the electrolysis were, except where otherwise stated, the same as in the preceding article.

Enclosure of Liquid.—It is extremely improbable that a smooth deposit of zinc would enclose a liquid, yet the best deposits are too high. Heating the dried deposit to 200° should reduce the weight, if any liquid were present. This was done repeatedly with different deposits and an insignificant increase in weight was always noticed, due, doubtless, to a very slow oxidation of the zinc. Further, electrolytic zinc that had been deposited from a solution that contained only sodium and zinc sulphates was carefully washed with water, alcohol and ether successively, dried and weighed. This weight was found to be invariably too high, if all the zinc had been deposited from solution. These deposits were next dissolved in hydrochloric acid, evaporated almost to dryness and the residue dissolved in a few cc. of water. On adding barium chloride not a sign of turbidity resulted on long standing. If any of the liquid had been enclosed some turbidity must have been in evidence under the conditions of the experiment. The last argument would also apply if any salt had been precipitated with the zinc.

Hydrogen Adsorbed or Deposited with the Zinc.—That any appreciable quantity of hydrogen is not contained in the deposits was proven in the following manner: About 0.4 gram of zinc was deposited on a copper gauze electrode from a sodium acetate solution. The deposit was in every case from 0.7 to 2.0 per cent. too high, which would correspond to 3 to 8 mg., or 40 to 100 cc. of hydrogen gas. The gauze electrode with the zinc deposit was put into the ignition tube *A* (Fig. 1) and covered with mercury. Flask *B* was filled to the neck with water and connected with the water in *C* by a short tube. *B* served as a trap to catch any mercury that might distil over. *C* was a 100 cc. graduated tube and was connected with the water in *D*. The mercury was boiled in *A* for 20 minutes. When the apparatus had cooled the water rose in *C* to the same level at which it stood before the heating. If any hydrogen had been contained in the zinc deposit it would have been given off and caught in *C* when the zinc formed an amalgam with the mercury.

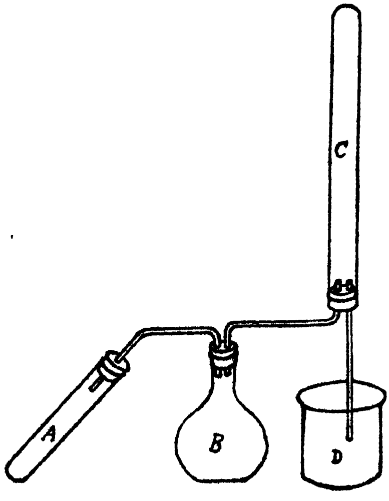

Fig. (1).

Metal Deposited with the Zinc.—If the high results were caused by the presence of a foreign metal, such as sodium, in the deposit, then there should be some relation between the magnitude of the error and the concentration of the sodium salts present during the electrolysis. This proved not to be the case, although the concentration was varied from zero to 200 grams per liter. Furthermore, two of these deposits were analyzed for sodium as follows: About one-half gram of the deposit was dissolved in hydrochloric acid and the zinc precipitated with ammonium carbonate. After acidifying with hydrochloric acid the filtrate was evaporated to dryness and the ammonium salts expelled. On once more precipitating the remaining zinc in a small volume with ammonium carbonate and expelling the ammonium salts the residue was not weighable. 10 to 20 mg. of sodium chloride must have remained if the high results are to be accounted for by the presence of sodium in the deposits.

Zinc Oxide or Hydroxide Deposited with the Zinc.—An attempt was made to reduce the zinc oxide by heating the deposit in a current of hydrogen gas. Owing to the volatility of the zinc and also of the zinc oxide, this was found to be impracticable. Reasons for believing in the presence of the oxide, or hydroxide, in the deposit are given below:

Zinc deposits from sulphuric acid solutions, where impoverishment of zinc in the cathode portion is prevented, have highly reflecting metallic surfaces and are found to be pure zinc by the best gravimetric methods. This was proven in the following manner: One gram of zinc sulphate was dissolved in 50 cc. of water to which was added 1 cc. of sulphuric acid (1.20). A rotating platinum crucible was made the cathode, pure zinc the anode, and the zinc deposited with a current of one ampere. The deposit was washed with water, alcohol, and ether, respectively, dried and weighed. The zinc was then dissolved in a few cc. of hydrochloric acid and the crucible again weighed. The zinc was determined by the phosphate method.[1] The results were as follows:

Elec.	Zn taken.	Zn found
1	0.1890	0.1891
2	0.1837	0 1841
3	1.1054	1.1040

Zinc deposits from neutral or dilute alkaline solutions have little or no metallic appearance. Those from acetate or oxalate solutions are dull gray. The upper portion of the deposit is often quite white, resembling zinc hydroxide. Deposits from strongly alkaline solutions are gray to black, depending upon the fineness of division of the metal; they are never smooth or metallic if the cathode portion becomes impoverished with regard to zinc. These finely divided, black deposits decompose water so rapidly, if sodium salts are present, that the bubbles of hydrogen gas can be seen rising from the surface of the metal. If they are wet with water and let dry in a desiccator they increase in weight and become quite white.

---

[1] Talbot, "Quantitative Analysis," p. 64. Dakin, *Ztschr. anal. Chem.*, 39, 273 (1900).

Pure zinc deposits obtained from sulphuric acid solutions increase in weight and become white and non-metallic on the outside if made cathode for some time in a nearly neutral or slightly alkaline solution. In very dilute sulphuric acid solution (10 cc. (1.20) per liter) the appearance and weight do not change. In strongly acid or alkaline solutions the zinc dissolves faster than it is reprecipitated by the current, and the weight of the electrode consequently decreases. This is shown by the following experiments:

Pure zinc deposits were obtained from sulphuric acid solution according to the method already given. They were then dried, weighed, made cathode in a neutral sodium acetate solution free from zinc and electrolyzed for 30 minutes with a current density of 2.5 amperes. The results are given below. Column 1 is the weight of the zinc obtained by the deposition from dilute sulphuric acid solution; column 2 gives the weight after 30 minutes:

1.	2.	
0.1833	0.1839	Deposits became non-metallic in appearance.
0.5202	0.5237	" " " "
0.2499	0.2508	" " " "
0.2787	0.2787	Very dilute acid. No change in appearance.
0.1810	0.1783	Acid stronger. No change in appearance

In order to prove that the oxidation of the zinc did not take place after the electrolysis while the electrode was being washed and dried, the following experiments were carried out: 0.2 to 0.4 gram of zinc was deposited from a sodium acetate solution according to the best methods that we have found. Copper gauze was employed as cathode and the deposits were all excellent. When the electrolysis was finished, without disconnecting the current or stopping the electrode, the solution was gradually replaced by water, alcohol and ether, respectively, and finally with ether that had been dried with sodium. The electrode, completely submerged in ether, was now put into a covered dish and the ether evaporated off in a current of hydrogen. In this way the deposit was never allowed to come in contact with the air until the zinc was quite dry. It would, therefore, be impossible for the oxidation of the zinc to take place after the electrolysis. The results of several analyses carried out in this manner are given below. Column 1 gives the weight of pure zinc taken and column 2 the weight of the deposit:

1.	2.
0.2106	0.2129
0.2439	0.2472
0.2513	0.2592
0.2671	0.2855
0.2843	0.2894
0.2713	0.2747
0.3014	0.3033
0.3177	0.3238

When solutions of sodium acetate are electrolyzed they become alkaline, owing to the formation of sodium hydroxide at the cathode and the oxidation of the acetate to carbon dioxide and subsequent escape of this gas at the anode. If the solution is not sufficiently concentrated with respect to sodium acetate the zinc will be precipitated out as hydroxide as soon as the solution becomes alkaline. If too much free acid is present all the zinc cannot be precipitated. If an excess of the acid is avoided, then the layer of liquid in the immediate neighborhood of the cathode becomes slightly alkaline, zinc hydroxide is formed in this layer and is precipitated with the zinc, possibly because it is enclosed or adsorbed.

The most obvious remedy that suggests itself would be to make the solution so strongly alkaline that the formation of zinc hydroxide would be impossible. This has been found to be impracticable because hydrogen is evolved so rapidly at the cathode that the character of the deposit is destroyed as soon as the solution becomes depleted with respect to zinc. Furthermore, strong alkaline solutions attack zinc deposits, especially those that are finely divided, so vigorously that it is almost impossible to completely precipitate the zinc. If the current density is increased, the solution foams because of the rapid evolution of hydrogen and a bad deposit results.

Theoretical Considerations.—A certain potential exists between a pure zinc electrode and a solution of zinc salts of given concentration. This potential depends upon the concentration of zinc ions, not upon the total amount of zinc in the solution and increases as the concentration of the zinc ions decreases. Therefore the applied electromotive force necessary to deposit zinc from a solution of its salts must be increased as the electrolysis proceeds. These facts are expressed mathematically by the following well-known equation:

$$\pi_{Zn \rightarrow soln} = E_{Zn} - (RT/2F)\ ln\ C_{Zn^{++}} \qquad (1)$$

π is the fall of potential in volts between the electrode and the solution, E_{Zn} is a constant equal to π when the concentration of the zinc ions is unity, R is the gas constant, F one Faraday's equivalent, C the concentration of the zinc ions in gram mols. per liter.

A similar equation must apply to hydrogen at atmospheric pressure surrounding a reversible electrode and a solution containing hydrogen ions:

$$\pi_{H_2 \rightarrow soln} = E_{H_2} - (RT/2F)\ ln\ C^2_{H^+}. \qquad (2)$$

If the hydrogen electrode is taken as zero, the potential between pure zinc and a normal solution of its ions is 0.77 volt.[1] The limiting concentration at which zinc can be quantitatively determined is about 10^{-5}. Assuming complete dissociation and putting these values in equation

---

[1] Wilsmore, *Z. physik. Chem.*, 35, 308.

(1) we get as a result 0.91 volt. The potential of the hydrogen electrode aginst a neutral solution calculated by equation (2) is 0.41 volt. It would, therefore, be impossible to precipitate zinc electrolytically from a neutral solution were it not that the overvoltage of hydrogen on zinc electrodes is high. For actual working conditions, then, we must add to equation (2) another term, η, which is a variable and is dependent upon the nature of the electrode and upon the current density.

By decreasing the concentration of the hydrogen ion *i. e.*, by making the solution alkaline, it would be more and more difficult to evolve hydrogen at the electrode. Unfortunately, however, the concentration of the zinc ion is diminished to a far greater extent than that of the hydrogen ion by the addition of a base, and thus the conditions are still more unfavorable for the complete precipitation of the zinc. This is apparent from the following considerations:

The equilibrium equation for the dissociation of water is

$$(H)(OH) = K_1 \text{ or } (H)^2 = K_1^2/(OH)^2. \qquad (3)$$

Zinc hydroxide is an amphoteric electrolyte and therefore dissociates both as an acid and as a base. For the dissociation as an acid we have the equation

$$(H^+)^2(ZnO_2^{--})/(Zn(OH)_2) = K_2. \qquad (4)$$

As a base,

$$(Zn^{++})(OH_2^-)^2/(Zn(OH)_2) = K_3. \qquad (5)$$

Substituting (3) in (4) we get

$$K_1^2(ZnO_2^{--})/(OH)^2(Zn(OH^-)_2) = K_2. \qquad (6)$$

Dividing (5) by (6) and transposing we get

$$(Zn^{++})(OH^-)^4/(ZnO_2) = K_3K_1^2/K_2 = K_4.$$

We see, then, that while the concentration of the hydrogen ion is inversely proportional to the concentration of the hydroxyl ion raised to the first power, that of the zinc ion is inversely proportional to the concentration of the hydroxyl ion raised to the 4th power. From these considerations, in connection with equations (1) and (2), it will be easily seen that it becomes relatively more and more difficult to precipitate zinc as we increase the concentration of the hydroxyl ion.

Summary.

In this article it has been experimentally shown that the high results obtained in the electrolytic determination of zinc are not caused by the enclosure of liquid, presence of a salt, hydrogen in the deposit, nor by the presence of another metal. The true cause is the deposition of zinc oxide or hydroxide with the zinc.

Theoretical considerations for the electrodeposition of zinc have been discussed and reasons for the rapid evolution of hydrogen in strong alkaline solutions have been given.

NOTES.

Titration of Ferrous Salts in the Presence of Hydrochloric and Phosphoric Acids.—Referring to a recent article by Elwyn Waller concerning the use of calcium phosphate in solutions containing hydrofluoric acid, when the solution is to be titrated by potassium permanganate, to obviate the bad effect of the hydrofluoric acid on the permanganate, it seems to me that the beneficial agent in this reaction is really the phosphoric acid.

I wish to state that the use of phosphoric acid alone in iron solutions to be titrated by potassium permanganate was first proposed by me about two years ago; my experiments and conclusions were published in the *Western Chemist and Metallurgist*, for Nov., 1907.

In trying to devise an improved method for the determination of iron in bone-black (which is nearly pure calcium phosphate), I found that the solution acidulated with hydrochloric acid could be titrated directly by permanganate, with great accuracy, the results checking with those made by the standard bichromate method, to hundredths of a per cent.

As the hydrochloric acid present seemed to have no effect on the permanganate, I reasoned that this must be due to the action of the phosphoric acid.

The method as applied to bone-black was as follows: The hydrochloric acid solution of the bone-black, after filtering off the carbon, was nearly neutralized by sodium carbonate to faint opalescence, then acidulated with 1 or 2 cc of concentrated hydrochloric acid, the carbon dioxide expelled, the solution reduced by addition of sodium sulphite, the sulphur dioxide expelled, the solution diluted with cold water to about 300 cc., and titrated with potassium permanganate.

After securing such favorable results on bone-black, I was impelled to try the method in the titration of iron in iron ores. I found it worked perfectly and gave extremely accurate results, provided one or two precautions were observed, namely, the use of a minimum amount of hydrochloric acid, not over five to ten cubic centimeters of concentrated acid, at the most, titration in a cold solution of about 300 cc. volume, and the avoidance of stannous chloride in reducing the iron.

The iron may be advantageously reduced by sodium sulphite, by aluminium, by zinc, or by test-lead. If test-lead be used, the reduction may be satisfactorily accomplished in a strongly acid solution, or in one that has been almost neutralized by sodium carbonate; and where we cannot avoid the presence of much hydrochloric acid, this reduction by test-lead in a nearly neutral solution would appear to be the best; or we can use zinc dust (powder), which also acts most rapidly in a nearly neutral solution.

It must not be thought that this improvement is simply a modification of the old Zimmerman-Reinhardt method. In that method, the manganese sulphate takes up hydrochloric acid, becoming manganese chloride, and the phosphoric acid present was supposed simply to decolorize the ferric iron and keep the solution colorless. But we see now that the phosphoric acid really plays a double rôle, and the addition of manganese sulphate and sulphuric acid is not at all necessary.

As the titration of iron solutions by potassium permanganate is much the preferable method in technical work, owing not only to its rapidity and ease of execution, but also to the sharpness of the end reaction, it seems to me that any suggestion that will tend to improve the method and make it more general of application cannot fail to be of great value to technical chemists generally. GEORGE J. HOUGH.

The Action of Coke on Solutions of Ferric Chloride.—In a previous communication[1] the author gave some data showing the extent to which iron is removed from a solution of ferric chloride by filtration through coke.

The opinion was then expressed that this action was largely due to sulphur compounds which had not been wholly removed from the coke.

A new series of experiments has been made to test this view, such precautions to eliminate sulphides from the coke being taken as the author's slender laboratory equipment would permit, and the results have confirmed the author in his opinion. The conclusion is, in brief, that no iron was taken up by coke so treated, from an approximately decinormal solution of ferric chloride under a variety of conditions, though a part of the salt was reduced to the ferrous condition. Coke similarly prepared did not abstract any copper from an approximately decinormal solution of cupric chloride. This last is in accord with the statement of W. O. de Coninck,[2] who, however, originally stated that the iron was abstracted from ferric chloride solution.

The following are the details of the new experiments:

Preparation of Coke.—Ordinary coke was ground and passed through a sieve of 100 meshes to the inch. It was then treated with hydrochloric acid, and after that with a mixture of concentrated hydrochloric and nitric acids. After standing a few days the acids were decanted off and the coke washed repeatedly with water, dried in the air and on the steam bath. Any higher temperature was avoided lest by local superheating residual sulphates should be converted into sulphides. The coke so treated, when heated with hydrochloric acid, gave no fumes capable of darkening lead test-paper.

Ferric Chloride Solution.—To a concentrated and acid solution of ferric chloride, sodium carbonate was added in such quantity that, though still acid to litmus, the color became essentially that characteristic of basic chloride. The solution was then diluted to the desired strength. Titration with standard potassium dichromate showed 1 cc. = 0.0053017 gram iron.

---

[1] THIS JOURNAL, 31, 461.

[2] *Compt. rend.*, 130, 1551.

In each experiment 40 grams of coke and 100 cc. of ferric chloride were used.

Experiment 1.—The solution was percolated, with the help of a filter pump, through the coke contained in a "Jones reductor" tube. The percolated liquid was then passed through a dry filter paper.

Experiment 2.—Coke was placed in a flask and ferric chloride solution was added to it. The flask was stoppered and allowed to stand 24 hours; its contents were then filtered through a dry paper.

Experiment 3.—Similar to Experiment 2, but that the time was 1 hour only.

Experiment 4.—Similar to Experiment 3, but that a portion of the mixture was removed and filtered after standing only 15 minutes, while the remainder was allowed to stand for a whole hour, so that two separate filtrates were obtained.

Each of the filtrates from the foregoing experiments was titrated with potassium dichromate after treatment with stannous and mercuric chloride in succession. It was found that, as before being in contact with the coke, 1 cc. in each case contained 0.0053017 gram iron. Under the conditions of each experiment it was found that a part of this iron had been reduced to the ferrous state, but the amount of this reduction was in no case determined.

Experiment 5.—A solution (as nearly as possible neutral) of cupric chloride was substituted for that of ferric chloride, but the conditions were otherwise as in Exp. 3. The concentration of the cupric chloride solution was such that 1 cc. = 0.006301 g. Cu. It was unaffected by the addition of the coke, as proved by subsequent titration with sodium thiosulphate.

TIENTSIN, CHINA.

Note on the Paper Entitled "Some Organic Tungstates."—In the June number of the JOURNAL I published a brief paper entitled "Some Organic Tungstates." The paper described and identified a number of tungstates of aliphatic amines. I have since received a letter from Dr. Lederer, of the Westinghouse Metallfaden-Gluhlampenfabrik, claiming priority and enclosing a copy of English patent No. 27,002, 1906, in which the following statement occurs:

"For this purpose advantage is taken of the fact that the trioxides and acid hydrates of the said metals (tungsten and molybdenum) combine with ammonia or with mono- and polyamines to form salts, and these salts, either alone or mixed together, with or without the addition of other tungsten or molybdenum compounds or of the metals themselves, are formed into a paste by the addition of an agglutinant, which paste is formed into filaments which are then heated."

From the above it is evident that Dr. Lederer experimented with compounds of tungsten, similar to those described in my paper, with a view to their use in the incandescent lamp industry, but did not isolate the compounds nor determine their composition by analysis. This was the main purpose of my paper. JOHN B. EKELEY.

PARIS, January 10, 1910.

THE BASIC PROPERTIES OF OXYGEN: COMPOUNDS OF DIMETHYLPYRONE AND THE HALOGEN HYDRIDES.

BY D. MCINTOSH.

Received February 12, 1910.

In 1899 Collie and Tickle[1] produced crystalline compounds by the addition of various acids to dimethylpyrone. They showed that neither water nor carbonic acid was eliminated by this treatment and that a simple ratio existed between the molecular quantities of the two reacting substances. To explain their results in terms of the current valency theory, they advanced the view suggested many years earlier by Friedel, that in certain compounds oxygen may act as a tetravalent element (the oxonium theory).

Since Collie and Tickle's paper appeared, additive complexes of substances containing oxygen have been widely studied by Baeyer and Villiger, Kehrmann, Hantzsch, Werner and many others.

The salts of dimethylpyrone have naturally undergone careful investigation. Collie and Steele[2] have produced compounds with iodine and hydriodic acid, Weinland and Reischle[3] combinations with hydrofluoric acid, while Plotnikov[4] has described basic and acid salts with chloro- and bromo-acetic acids. The constitutions of these compounds are explained by the assumption of a tetravalent oxygen atom or by the subsidiary bonds according to Werner's theory.

In Collie's first paper dimethylpyrone was represented as a ring containing two divalent oxygen atoms, which for discussion may be termed the ethereal and the carbonyl oxygen atoms. The salts of dimethylpyrone were supposed to have the acid attached to the ethereal oxygen atom, although no reason for its selection was given; and the compounds were represented as

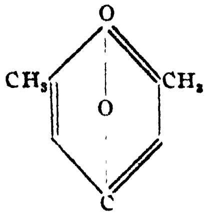
[2] *Ibid.*, 77, 1114 (1900).

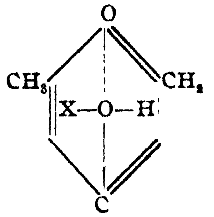
[3] *Ber.*, 41, 3671 (1908).

[4] *Ibid.*, 42, 1154 (1909).

Recently Collie[1] has changed his views regarding the composition of the pyrone and its salts. The former is supposed to have a tetravalent oxygen atom, and in the latter the acid is attached to the carbonyl oxygen atom. The constitutions given are:



and



This hypothesis is strengthened by the work of Homfray[2] and also by the spectroscopic measurements of Baly.[3] On the other hand, Willstäter and Pummerer[4] give reasons why the pyrone itself cannot have a tetravalent oxygen atom and inferentially why its salts cannot have the formulas attributed to them.

In a former paper[5] I attempted to show that some of the compounds regarded by Baeyer and Villiger as containing tetravalent oxygen atoms were merely cases of solid solution, while others formed from hydroferrocyanic acid and the alcohols did not differ in structure from salts with alcohol or water of crystallization. Dimethylpyrone, like ferrocyanic acid, is a solid at ordinary temperatures, and since its salts might be looked on as pyrone with "acid of crystallization," I have examined some of its compounds over a considerable temperature range.

Materials.—The dimethylpyrone was purchased from Merck. No process of purification was thought necessary as its salts of the halogen acids were identical with those described by Collie and Tickle. The halogen hydrides were prepared and liquefied in the ordinary way. The hydrogen fluoride was obtained by distillation of a pure solution of the acid, and experiments with it were carried out in platinum vessels.

Since the formation of compounds is often indicated by electrical conductance in solution, measurements of dimethylpyrone in hydrogen bromide at —78° and in hydrogen chloride at —100° were made. The results are given in the tables and shown in the diagram:

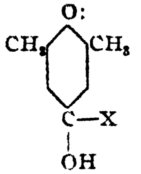
Dimethylpyrone itself cannot be looked on as an electrolyte. It must unite with the hydrobromic acid, otherwise the conduction of electricity would be impossible. The union cannot take place with a halogen and hydroxyl attached to the carbon, as suggested by Werner, for this compound



should not be ionized. The pyrone moves to the cathode during electrolysis, so the halogen is not attached to the oxygen by a double bond. Further, since the molecular conduction increases with concentration—as it does with all substances containing oxygen and nitrogen in these solvents—complex ions must be formed.[1] We may thus expect compounds in which the pyrone and acid are not present in equimolecular proportions.

Hydrochloric Acid Compounds.—A solution of dimethylpyrone in aqueous hydrochloric acid was kept in a vacuum desiccator till dry. It contained 22.6 per cent. acid and was, therefore, $C_7H_8O_2HCl$. Another specimen, dried between filter papers, gave 19 2 per cent. acid, corresponding to $C_7H_8O_2HCl.2H_2O$. These compounds were first prepared and described by Collie and Tickle.

Dimethylpyrone dissolves readily in liquefied hydrogen chloride with an evolution of heat, noticeable, but small compared with that given by ether, etc. A crystalline substance soon separates out, which melts sharply at —25°. Analyses of different preparations gave 42.6, 45.5, 44.1 and 42 7 per cent. acid. $C_7H_8O_2.2HCl$ contains 36.4, $C_7H_8O_2.3HCl$, 46 9 per cent.

Evidence of the existence of a more complex compound with a much lower melting point was obtained. The difficulty of removing the excess of acid was so great that this body was not examined further.

Hydrobromic Acid Compound.—From an aqueous solution of hydrobromic acid and dimethylpyrone compounds containing from 39.3 to 40 per cent. acid were produced. By dissolving the pyrone in the anhydrous acid and allowing the excess to evaporate salts with 38.9, 39 2, 38.4, 39.3 per cent. acid were made at various times. $C_7H_8O_2HBr$ contains 39.5 per cent. acid (Collie and Tickle). In anhydrous hydrogen bromide dimethylpyrone forms an oily liquid which dissolves easily. At the saturation point a compound probably containing one molecule of acid appears and this floats on the hydrobromic acid and dissolves but slowly. When the saturated solution is allowed to stand or when a crystal of the pyrone is added quickly with a stirrer, prismatic crystals (probably orthorhombic) with faces appear. These crystals give, on analysis:

Sample I,	74.7; 75.1 per cent. acid.
Sample II,	74.2; 75.1 per cent. acid.
Mean,	74.8 per cent. acid.

---

[1] Steele, McIntosh and Archibald, *Z. physik. Chem.*, 52, 129 (1906).

This compound is doubtless $C_7H_8O_2 4HBr$, which contains 72.3 per cent.

When warmed, the tetrahydrobromide melts sharply at —59°, the excess of acid quickly evaporates, and a solid reappears. This substance has a high vapor pressure and when "dried" at —35° contains 59.5, at - 13° 53.2 per cent. acid, which corresponds to $C_7H_8O_2 2HBr$. It melts at —2° and is converted into the compound containing one molecule of acid. Vapor pressure measurements have failed to show the existence of a compound containing three molecules of acid.

Hydriodic Acid Compounds.—Dimethylpyrone dissolves, but less readily, in hydrogen iodide than in the bromide, and at a low temperature crystals separate out. These contain 83.3, 83 6 and 84.6 per cent. acid in three preparations, while $C_7H_8O_2.4HI$ has 82 2 per cent.

At —42°, $C_7H_8O_2.4HI$ melts and a substance with 69 8 per cent. acid separates, which in its turn liquefies at + 7° and yields $C_7H_8O_2HI$. A compound of one molecule pyrone and two of hydrogen iodide contains 67 4 per cent. acid.

Hydrofluoric Acid Compounds—Since fluorine does not unite directly with oxygen, oxonium compounds with hydrofluoric acid should prove of the greatest interest. Landolph[1] claims to have produced two substances in which hydrogen fluoride was united with acetone, and quite recently Weinland and Reischle[2] describe two dimethylpyrone hydrofluorides. The formula $C_7H_8O_2.3HF.0\ 5H_2O$ is given to one prepared from the aqueous acid, the other from an alcoholic solution is represented as $C_7H_8O_2 3\ 5HF0\ 5H_2O$.

Stable compounds of pyrone and hydrofluoric acid are not easy to prepare. In one experiment an aqueous solution of acid and dimethylpyrone was kept over sulphuric acid and potash in a vacuum desiccator. When dry the salt contained 20 3 per cent. acid. After two weeks the acid content had fallen to 15.1 per cent.; two weeks later to 13 1; and after standing two months longer, only 10 7 per cent. acid remained.

A crystalline preparation, made with a large excess of acid, when dried between filter papers, held 37 7 per cent.; after two weeks in a desiccator this was reduced to 30.8 per cent. acid.

A third sample, made by mixing pyrone and acid in approximately molecular proportions, gave, when dried, 14.9 per cent. acid; after two weeks further drying, 13.9 per cent., which corresponds to the formula $C_7H_8O_2HF$. But after five months the acid had fallen to 9.6 per cent. If compounds of dimethylpyrone and hydrofluoric acid are formed they are neither so simple nor so stable as those with the halogen hydrides.

---

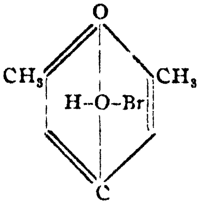
[1] *Compt. rend.*, 86, 1463; 96, 580.

[2] *Loc. cit.*

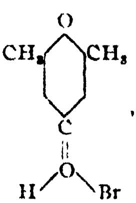
Note.—Anhydrous hydrofluoric acid is unlike the halogen hydrides. When treated with ether, acetone, etc., much less heat is evolved and compounds, if formed, do not crystallize out easily.

We have seen that hydrobromic acid unites with dimethylpyrone to give three stable compounds containing one, two and four molecules of acid. Since hydrobromic acid does not polymerize even when liquefied, any theory to explain the linking of the acid in the simplest compound should apply equally well to the others. We may regard these additive compounds as pyrone with "acid of crystallization," or we may ascribe formulas to them in which oxygen has a higher valency than two.

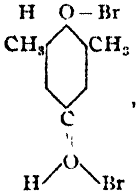
If we accept Collie's representation of the constitution of dimethylpyronehydrobromide,



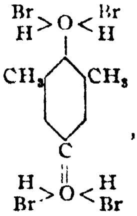
it is difficult to give a satisfactory explanation of the formation of the other salts, unless we admit the possibility of the linking between the two oxygen atoms being broken at such a low temperature. But if we regard the dimethylpyrone itself as a substance with two divalent oxygen atoms we may represent the three salts as



,



,



,

the first containing one, the second two tetravalent, and the third three hexavalent oxygen atoms.

In the most complex salt the oxygen is supposed to function as a hexad, and this may be objected to as unusual and unnecessary. Yet the same arguments advanced for the tetravalency of oxygen apply equally strongly to its hexavalency here; and the position of this element in the sixth column of the periodic table permits the view that its valency may vary as does that of sulphur, selenium and tellurium.

ELEMENTARY ANALYSIS BY MEANS OF A CALORIMETRIC BOMB.

BY HAROLD L. HIGGINS AND ALICE JOHNSON.

Received January 24, 1910.

Since the complete oxidation of organic material, with the quantitative conversion of carbon to carbon dioxide, and of hydrogen to water, presents the greatest difficulty in elementary organic analysis, it is not surprising that particular attention has been paid to making use of the ideal conditions of oxidation obtained inside of a calorimetric bomb. Burning substances in oxygen at a pressure of 25 atmospheres results, usually, in complete oxidation with minor products of combustion, particularly the oxidation of a small amount of nitrogen to nitric acid.

One chief objection to the use of the bomb for ordinary elementary analysis has been the fact that about 1 gram of substance is required,[1] and in many instances, particularly in the field of organic chemistry where frequently but a small amount of material may be available, this precludes the use of the method. On the other hand, in many researches where both the heat of combustion and an elementary analysis are desired, the bomb can be used to great advantage.

In metabolism experiments, either with men or with animals, where it is desired to determine not only the energy ba'ance but likewise the carbon and hydrogen balance, elementary analysis by the bomb is of especial value. Under these conditions, it is necessary to determine both the heat of combustion of the food, feces, and urine, and the amount of carbon and hydrogen in these products; and the simultaneous determinations allow a great saving in time. Usually the substances to be dealt with are in sufficient quantities to permit of large samples, and of duplicate combustions. With coal and other fuels, simultaneous determinations of heat and elementary analyses may also be made where the percentages of carbon and hydrogen present in the coal are desired in addition to the energy value as represented by the heat of combustion.

The Determination of Carbon.—The most common method of determining carbon by the calorimetric bomb has been to collect, in potassium hydroxide or soda lime, all the carbon dioxide formed during the combustion of the substance and to weigh the amount collected. Berthelot,[2] and later Hempel,[3] determined carbon in this way, using a one-valve bomb. The last traces of carbon dioxide were removed by suction, the gas being swept out several times and the bomb refilled with dry air. The method is simplified, however, by using a bomb with two valves, as shown by Kröker[4] and Fries,[5] the bomb being eventually freed of carbon dioxide by passing air through it.

Zuntz and Frentzel[6] in 1897 suggested a method for making carbon determinations with the bomb, wherein they found the total weight or volume of the gases resulting from the combustion and by analyzing these gases, they were able to calculate the total amount of carbon dioxide present. Following this suggestion we have, under the direction of Professor Benedict, developed a method which seems to offer excellent opportunities for routine carbon analyses, which are sufficiently accurate for the most exact physiological experimenting. According to this method, we first weigh the gas at the end of the combustion and then determine the carbon dioxide in a sample by means of a Haldane gas analysis apparatus.[1] Knowing the weight of the gas, the percentage of carbon dioxide, and the amount of nitrogen present, we can calculate the amount of carbon dioxide present by the use of a formula obtained from the following equations:

---

[1] Hempel obviated this objection by the use of a small autoclave similar to the bomb, whereby smaller amounts of substance could be burned more satisfactorily, *Ber.*, 30, 202 (1897). See also Langbein, *Chem.-Ztg.*, 38, 1055 (1909).

[2] Berthelot, *Compt. rend.*, 114, 317 (1892), and 129, 1002 (1899).

[3] Hempel, *Loc. cit.*

[4] Kröker, *Z. Ver. Rubenzücker-Industrie*, 46, Heft 482. *Ber.*, 30, 606 (1897).

[5] Fries, This Journal, 31, 272 (1909).

[6] Zuntz and Frentzel, *Ber.*, 30, 380 (1897).

$$(1) \qquad x + y = c - a.$$

$$(2) \qquad (x/1.43 + y/1.966 + a/1.26)\, b/100 = y/1.966.$$

In these equations, a equals weight of nitrogen gas; b, per cent. carbon dioxide in gas; c, weight of gas; x, weight of oxygen; and y, weight of carbon dioxide. The gas in each instance is that in the bomb at the end of the combustion. Solving for y, we obtain:

$$y = (c + 0.137a)/(0.2727 + 72.73/b) = \text{weight of carbon dioxide},$$

or

$$\text{the weight of carbon}^{2} = 3y/11 = (c + 0.137a)/(1 + 266.67/b)$$

Thus, having the total weight of carbon in the bomb, the percentage of carbon in the substance is readily obtained, after applying corrections for the carbon in the kindler, in the igniting thread, and in the oxygen used.

The Determination of Hydrogen.—Berthelot[3] suggested that the bomb may be used in determining hydrogen by driving out all of the water as vapor and absorbing and weighing it in a dehydrating agent, such as concentrated sulphuric acid or calcium chloride. He immersed the bomb in a water bath and exhausted and admitted air alternately. Kröker,[4] with a two-valve bomb, was able to simplify this process, but the method has the following decided disadvantages: (1) The presence of nitric acid (as well as sulphuric acid, when the substance burned contains sulphur) makes it difficult to expel all of the water and nothing else, and furthermore, these acids tend to attack the valves of the bomb; (2) the heating of the bomb in the bath also increases the liability to injure the enamel lining; (3) it is very difficult to get the interior of the bomb perfectly dry at the beginning of the combustion, as is necessary when this method is used; (4) the operation is very time-consuming.

---

[1] Haldane, *J. Physiol.*, 22, 465 (1897).

[2] 0.137 represents (molecular weight oxygen/molecular weight nitrogen) — 1; 266.67 represents 100 molecular weight oxygen/atomic weight carbon.

[3] Berthelot, *loc. cit.*

[4] Kröker, *loc. cit.*

Langbein[1] determined the water formed by placing a drying glass containing phosphorus pentoxide within the bomb, expelled most of the nitric acid by passing air through the bomb in a bath at 100°, and determined the sulphuric acid by titration. Hempel,[2] using a small autoclave similar to the bomb, drove out only a part of the water, and collected it in a calcium chloride tube. The remainder was weighed in the autoclave itself, the water representing the difference in weight of the autoclave when empty as compared with its weight after the combustion gases had been swept out, corrections being applied for nitric acid, for ash, and for the water formed from the kindler. We have applied Hempel's method to the bomb, modifying it somewhat to assist in making the determination more rapid and better adapted to routine work. The method of calculation of the water formed is easily understood from the following equation:

Weight of water formed $= d - e + f$, in which

d = Weight of bomb after combustion, when it contains combustion gases at 1 atmosphere pressure, — weight of gas in the bomb — weight of nitric acid formed — weight of ash.

e = Weight of bomb before charging with oxygen — weight of air it contains — weight of pellet — weight of ignition thread — weight of kindler (if used).

f = Weight of water leaving the bomb on releasing the pressure.

The percentage of hydrogen is then easily calculated, corrections being necessary for the hydrogen in the ignition thread, in the oxygen (if any is present), in the nitric acid, and in the kindler.

Description of Apparatus Used.

Calorimetric Bomb.—In this research we have employed a Kröker bomb, such as has been used by Jaeger and von Steinwehr,[3] and Fischer and Wrede.[4] The bomb is lined with enamel (although platinum may be substituted) and has a platinum-lined cover, and two valves with platinum-iridium points, one for the admission of oxygen and the other through which compressed air may be admitted to completely drive out the combustion gases if desired. The method of analysis here described is applicable, however, to a one-valve bomb. Instead of igniting the sample by iron wire, we use platinum wire, a cotton thread extending from this platinum wire to the substance to be burned; to ignite the sample, the current is passed through the platinum wire, raising it to incandescence and igniting the thread which, in turn, ignites the substance. A platinum cup is furnished with each bomb, but we find that the platinum deteriorates rapidly and we have therefore substituted nickel capsules;[5] a nickel wire support serves to hold the capsule in place.

Compressed Oxygen.—In all of the more recent experiments we have used Linde oxygen made from liquid air, which is free from carbon dioxide and combustible gases. Analyses made of this gas showed but 6 milligrams of carbon dioxide in 100 grams of oxygen, and we were unable to find an appreciable amount of hydrogen or hydrocarbons.

Balance.—For weighing the bomb in our analyses, we make use of a balance[1] on which one is able to weigh accurately a load of 10 kilograms to 0.01 gram.

Gas Analysis Apparatus.—For our gas analyses, we use the Haldane apparatus, with which analyses of carbon dioxide and oxygen can be made with an accuracy of 1 part in 500. As a compensating burette is used, variations in pressure and temperature of the outer air are without effect. For the finer adjustment of the level of the mercury, a screw pinchcock of special construction is so applied that after closing all communication with the leveling tube, a slight motion of the screw so alters the pressure on the rubber tube as to allow a very accurate adjustment of the mercury in the burette.

Method of Manipulation.

In a determination, the bomb is first cleaned. The substance to be burned is then weighed—with the capsule, if ash is present—and put into the bomb, the ignition adjusted, and the cover screwed on. The valve is opened and then closed to make sure that the interior is at atmospheric pressure and the bomb and contents are weighed to 0.01 gram. The bomb is next charged with oxygen to 20 or 25 atmospheres and again accurately weighed. The combustion follows, the bomb being placed in a calorimeter, if a determination of the heat of combustion of the material is also desired After the combustion, the bomb is carefully dried until it weighs exactly the same as it did before the combustion, so that the weighings taken after the combustion may be upon the same basis as those before.

The gas is released from the bomb, passing through a weighed U-tube containing sulphuric acid, then through the top of two T-tubes connected to two Haldane gas samplers previously filled with mercury, and finally bubbles through water. When the combustion gases have seemingly displaced the air previously in the system, the two gas samplers are filled with the gas by displacement of mercury, the mercury in the sample being lowered by means of a leveling bulb connected to the lower end of the sampler; then the gas in the sampler is put under pressure of mercury by closing the upper stopcock, and raising the leveling bulb on the outside. When the gas in the bomb reaches atmospheric pressure, the bomb is closed and weighed. It is then opened, the ash, if any, is weighed, and the rinsings are titrated for nitric acid. In determining the amount of nitric acid, we use the method of Stohmann, titrating with a solution of sodium carbonate of 0.003706 gram per cc.; 1 cc. of this solution is equivalent to 0.004406 gram of nitric acid, the heat of formation of which is 1 calorie. A table can readily be prepared showing the respective weights of nitric acid, hydrogen and nitrogen which the various volumes of sodium carbonate solution represent. With the analysis of the gas samples for carbon dioxide, all the data necessary for the determination of carbon and hydrogen are at hand.

---

[1] The balance, with glass case, was furnished through the Bausch & Lomb Optical Co., at a duty-free price of about $40.00.

The gas samples, being under pressure, need not be analyzed immediately but may be kept a week or longer, and a number of analyses made at the same time. The value of keeping the samples under pressure lies in the fact that if a slight leak occurs, some of the gas inside may escape, but none from without can enter the sampler. If, however, the gas samples have been kept for some time, they should be tested to find out if they are still under pressure, and if not, they should be discarded. When the analyses of the two samples show a marked difference, the one having the larger percentage of carbon dioxide is taken, as it is assumed that the other has air mixed with it; if the agreement of results is good, an average is taken.

In addition to collecting the sample over mercury, we have allowed the gas from the bomb to flow directly through the gas sampler and eventually displace all the air. To facilitate this displacement, the direction of the flow of gas is reversed during the operation. Duplicate analyses of gas from the same combustion show no differences in the two methods of sampling.

Calculation of Results.—From the data thus obtained, the computation follows. The formula used for computing the weight of carbon is:

$$\text{Weight of carbon} = (c + 0.137a)/(1 + 266.67/b).$$

The three factors, c, a, and b, are derived from the data previously obtained. c (the weight of gas in the bomb at the end of combustion) equals the weight of the bomb immediately after the combustion, less the weight of the bomb after all but 1 atmosphere of the combustion gas has been released, plus the weight of this atmosphere of gas (calculated from the table described later), less the weight of water passed out of the bomb and collected in the sulphuric acid U-tube.

The weight of nitrogen gas in the bomb at the end of the combustion, a, is found by adding the weights of nitrogen in the atmosphere of air in the bomb before the bomb is charged with oxygen, in the oxygen supplied, and in the substance burned, and from this total, subtracting the weight of the nitrogen oxidized to nitric acid. The weight of nitrogen in the air of the bomb before charging is constant for every bomb and is easily calculated from the volume. The weight of the oxygen added to the bomb is equal to the difference between the weights of the bomb before and after charging; the weight of nitrogen in this oxygen is obtained by multiplying the weight of oxygen by the percentage weight of nitrogen it contains.[1] The weight of nitrogen in the sample burned is calculated from a Kjeldahl analysis of the substance; if no Kjeldahl analysis has been made, an estimation of the quantity of nitrogen with an accuracy of 0.10 gram, may suffice, as an error less than this will not affect the percentage of carbon by more than 0.15 per cent.

The percentage of carbon dioxide by volume, *b*, is found with the Haldane apparatus. After the total amount of carbon in the oxygen, in the thread used for ignition, and in the kindler (such as naphthalene or benzoic acid) has been subtracted from the weight of carbon thus found, the percentage of carbon is obtained by dividing the weight of carbon by the weight of the substance. Assuming the cotton thread (0.006 gram) used for ignition is pure cellulose, the carbon in the thread is calculated.

In calculating the percentage of hydrogen, use is made of the following formula:

$$\text{Weight of water formed} = d - e + f.$$

d represents essentially the weight of the bomb proper and the water it contains, and is found by subtracting from the weight of the bomb at the end of a combustion (with the pressure released and but one atmosphere of combustion gases left behind) the combined weights of the nitric acid, of the ash present and of the atmosphere of combustion gases. This latter factor involves a knowledge of the volume of air space within the bomb and the composition of the gas. The volume of the air space in the bomb is a constant and is found by weighing the bomb full of water. The percentage of carbon dioxide is already known, and the percentage of nitrogen (6 to 7 per cent. when no nitrogen is present in the substance) is found to be sufficiently constant to make an analysis for nitrogen unnecessary. A table has been prepared showing the weights of gas occupying this space for the varying percentages of carbon dioxide and nitrogen. When the substance contains considerable nitrogen, the gas may be analyzed for nitrogen on the Haldane apparatus, or it is much simpler and sufficiently accurate to approximate the percentage of nitrogen;[2] this is accomplished by the proportion

$$x : 7 = a : 0.44.$$

In this proportion 7 equals the percentage of nitrogen gas usually obtained when no nitrogen is in the sample, *a* equals the weight of nitrogen gas present (*a* in the formula for determining carbon), and 0.44 equals the weight of nitrogen gas usually present, when no nitrogen is in the substance. The possible error in the percentage of hydrogen from using this formula is very small, an error of 3 per cent. in total nitrogen leading to an error of only about 0.0001 gram of hydrogen. The following table has been calculated for a bomb containing 275 cc. Intermediate values are easily found by interpolation.

---

[1] The percentage of nitrogen by volume is usually supplied by the manufacturer.

[2] With a two-valve bomb, one may sweep the combustion gas from the bomb with air and thus be able to deal with the weight of the bomb full of atmospheric air, instead of combustion gases. This would require more time and also a careful measurement of the water leaving the bomb.

It may be noted that this table is also used in the carbon determination in calculating the weight of gas in the bomb at the end of a combustion.

Per cent. CO_2.	Per cent. O_2.	Per cent. N_2.	Wt. 1 liter of gas. Grams.	Wt. of 275 cc Gram.
12	81	7	1.482	0.4076
14	79	7	1.493	0.4106

12	64	24	1.454	0.3999
16	60	24	1.475	0.4056
..	21	79	1.296	0.3564

e represents the weight of the empty bomb. This is found by subtracting from the weight of the bomb at the beginning of the experiment before charging with oxygen (1) the weight of air which it contains (see table), (2) the weight of the substance burned, and (3) the weight of the ignition thread and kindler.

f is the weight of the water leaving the bomb on releasing the pressure and collected in the sulphuric acid U-tube and has been found to be very constant (0.017 gram). Owing to the small variation in this weight, we have decided that we may safely discard the U-tube and assume the weight of water leaving the bomb to be 0.017 gram.

One-ninth of the weight of water thus found plus the weight of hydrogen in the nitric acid formed, minus the hydrogen in the ignition thread and in the kindler, gives the weight of hydrogen in the substance.

Specimen combustion.
(Nitrogen-free material.)

Cane sugar. Weight taken = 1.3117 grams

Weight of ignition thread	0.006	gram
Weight of bomb before charging with oxygen	2613.30	grams
Weight of bomb after adding oxygen	2621.62	grams
Weight of oxygen	8.32	grams
Weight of bomb after combustion gases are passed out	2612.82	grams
Gas analysis = 17.01 per cent. CO_2 Nitric acid =	0.034	gram
Weight of water leaving bomb on release of pressure	0.017	gram

Weight of gas in bomb at end of combustion with pressure released 0.415 gram (from table).

Weight of air in bomb at start of combustion, 0.356 gram (from table).

Percentage of carbon. Weight of carbon = $(c + 0.137a)/(1 + 266.67/b)$.

2621.62 8.32
—2612.82 ×1.6 per cent. (percentage of nitrogen in oxygen by weight).

8.80 0.1331
+0.415 +0.2737 nitrogen in air in bomb

9.215 0.4068
—0.017 —0.007 nitrogen in nitric acid.

9.198 = c 0.400 = a 17.01 = b

Substituting in this equation:

Weight of carbon = $[9.198 + (0.137)(0.400)]/[1 + 266.67/17.01] = 9.253/16.677 =$ 0.5548 gram.

0.5548
—0.0027 carbon in thread. (No carbon in the oxygen used.)

0.5521 carbon in sugar.
0.5521 ÷ 1.3117 = 42.09 per cent. carbon.

Percentage of hydrogen. Weight of water = $d - e + f$.

2612.82 2613.30
—0.415 —0.356

2612.405 2612.944
—0.034 —1.312 0.017 = f

2612.371 = d 2611.632
—0.006

2611.626 = e

Substituting, weight of water = 2612.371 — 2611.626 + 0.017 = 0.762 gram.

0.762/9 = 0.0847 gram = weight of hydrogen.

0.0847
+0.0005 hydrogen in nitric acid.

0.0852
—0.0004 hydrogen in ignition thread.

0.0848 gram hydrogen in sugar.
0.0848 + 1.3117 = 6.47 per cent. hydrogen.

Specimen combustion.

(Nitrogenous material.)

Urea. Weight taken = 1.9202 grams

Kindled by 0.0583 gram of benzoic acid.

Weight of ignition thread........	0.006 gram
Weight of bomb before charging with oxygen.............	2613 22 grams
Weight of bomb after adding oxygen...........	2620 87 grams
Weight of oxygen........	7 65 grams
Weight of bomb after combustion gases are passed out.....	2612.50 grams

Gas analysis = 14.135 per cent. CO_2. Nitric acid = 0 050 gram

Weight of water leaving bomb on release of pressure. ..... 0 017 gram

Weight of gas in bomb at end of combustion with pressure released 0 404 gram (from table).

Weight of air in bomb at end of combustion 0.356 gram (from table).

Percentage of carbon. Weight of carbon = $(c + 0.137\ a)/(1 + 266.67/b)$.

Gas in bomb contains approximately 21 per cent. nitrogen for:

$x : 7$ per cent. $= 1.29 : 0.44$ $x = 20^1/_2$ per cent.

2620.87
—2612.50

8.37
+0 404

8.774
—0.017

8.757 grams = c

7.65
×1.71 per cent. (per cent. nitrogen in oxygen).

—0.006

2610.880 = e

0.017 = f

Substituting, weight of water = 2612.046 — 2610.880 + 0.017 = 1.183 grams
1.183/9 = 0.1314 gram of hydrogen.

0.1314
+0.0008 hydrogen in nitric acid

0.1322
—0.0033

0.1289 gram hydrogen in urea

0.0004 hydrogen in ignition thread
0.0029 hydrogen in benzoic acid

0.0033

0.1289 ÷ 1.9202 = 6.71 per cent. hydrogen

In a carbon determination, the greatest liability to error rests with the gas analysis. An error of one-third of 1 per cent. in gas analysis should make a similar error of one-third of 1 per cent. in the result. Under the most adverse conditions, one should not make an error of greater than ±0 5 per cent. in these analyses and in the sampling. As the formula involves two weighings of the bomb, allowing each weighing is inaccurate to ±0.01 gram, a maximum error of ±0.02 gram is possible which would ordinarily be about ±0.2 per cent. in the total carbon. Errors from other sources would be so small as to be practically negligible, so that the total maximum error possible is ±0.7 per cent.

The hydrogen determination is liable to a slightly larger percentage error. Two weighings of the bomb being necessary, an error of 0.02 gram of water is possible, involving from 1 per cent. to 5 per cent. error in the hydrogen according to the amount of hydrogen in the substance. All the other data used in calculating the water are sufficiently accurate to involve an error of not more than 1 per cent. One or two features in the analysis for hydrogen require attention: the presence of hydrogen, or hydrocarbons, in the oxygen used will cause the formation of water in the bomb; if an oxygen cylinder contains even as small an amount as 0.02 per cent. of hydrogen by weight, as much as 0.0144 gram of water will be formed when using about 8 grams of oxygen in a combustion, thus introducing an appreciable error. We have tested several cylinders of Linde oxygen and failed to find hydrogen in any of them. Another seemingly apparent difficulty would be the action of oxygen and nitric acid upon the lead gaskets of the bomb. The lead when oxidized would increase in weight and this increase would be measured as water. Practically, it has been found by experiments that the lead gasket, although superficially oxidized, does not appreciably increase in weight; experiments with an aluminium gasket give results parallel to those with the lead, although with the aluminium gasket there is no apparent oxidation during combustion. It is seen that the liability of error in the hydrogen determination varies from 2 to 6 per cent., according to the amount of hydrogen present.

The following determinations give some idea of the fluctuations of the results of this method for determining carbon and hydrogen simultaneously.

NUTRITION LABORATORY OF THE CARNEGIE INSTITUTION OF WASHINGTON,
VILA ST., BOSTON, MASS.

THE COMPOSITION OF SOME BENGALI FOOD MATERIALS.

BY HOPE SHERMAN AND H. L. HIGGINS.

Received January 24, 1910.

The importance of a knowledge of the dietetic habits of various nationalities was frequently emphasized by the late Professor W. O. Atwater. In connection with an extensive investigation into the food and diet of different classes of people in America, which was instituted by him and carried out under his direction, considerable material was collected regarding the dietetic habits of other nationalities, especially those of the Chinese and Japanese.[1] These data show that many popular impressions regarding the diet of people in foreign countries are erroneous. Particularly is this true with regard to the relative proportions of animal and vegetable food and with regard to the amount of protein ingested.

While considerable information has been gathered concerning the food and diet of Europeans and Americans, with the exception of the publications previously referred to, but a small amount of data is available regarding the dietetic habits of the swarming population of Asiatic countries. Of especial interest, therefore, is an investigation of the highest scientific accuracy as to the food and diet of various classes of people in India, which has been undertaken within the last few years by Captain D. McCay, of the Calcutta Medical College. Captain McCay first studied the dietetic habits of the Bengalis, who are practically vegetarians, living for the most part on rice and dhall (pulse). The results of this study have been published in a memoir,[1] in which Captain McCay points out the noticeable peculiarities in the dietetic customs of the Bengalis, and discusses their bearing upon the physical development and endurance of this class of people.

[1] Blasdale, "A Description of Some Chinese Vegetable Food Materials and Their Nutritive and Economic Value," U. S. Dept. Agr., Office Exp. Sta., *Bull.* 68 (1899). Jaffa, "Nutrition Investigations among Fruitarians and Chinese at the California Agricultural Experiment Station, 1899–1901," U. S. Dept. Agr., Office Exp. Sta., *Bull.* 107 (1901); Jaffa, "Further Investigations among Fruitarians at the California Agricultural Experiment Station," U. S. Dept. Agr., Office Exp. Sta., *Bull.* 132 (1903). Oshima, "A Digest of Japanese Investigations on the Nutrition of Man," U. S. Dept. Agr., Office Exp. Sta., *Bull.* 159 (1905).

Inasmuch as the heats of combustion of the typical foodstuffs studied were not determined by Captain McCay, it seemed desirable to secure definite evidence with regard to these values, and arrangements were made by Professor F. G. Benedict, Director of the Nutrition Laboratory, to secure from Captain McCay samples of the food materials used in the investigations. A collection of these samples was sent to the Nutrition Laboratory from India in air-tight cans, and the analyses have been made and the heats of combustion determined by us.

As soon as the samples were received, they were ground and placed in well-stoppered, sealed bottles; determinations were then made of the water, nitrogen, fat, and heat of combustion. All the determinations were made in duplicate, frequently in triplicate, and the results are given in the table herewith.

The water was determined by prolonged desiccation in a high vaccum, according to the method of Benedict and Manning.[2] The nitrogen determinations were made by the Kjeldahl method, which was carefully checked by the determination of nitrogen in pure uric acid. The determinations of the fat were made in a special apparatus designed by Winton. The heat of combustion was determined in a Kröker calorimetric bomb by means of a new form of adiabatic calorimeter, designed by Benedict and Higgins.[3] The hydrothermal equivalent to the calorimeter system was so taken that the heat of combustion of pure cane-sugar was 3959 calories per gram.

For purposes of comparison, the composition of various American food materials, as given by Atwater and Bryant,[4] is included in the table. Thus, wheat and wheat ata (the latter, a flour obtained by grinding wheat) are compared with the ordinary grades of American wheat flour; makkai ata, with corn meal and corn; dhall (pulse), with the dried peas used in this country; and rice, with the ordinary uncooked rice of commerce. Certain determinations which have been made by Captain McCay on these food materials and published by him in the memoir referred to have also been included in the table under the heading "Calcutta analyses."

[1] Different factors for computing the protein of the various classes of food materials have been proposed by Atwater and Bryant (see Rept. Storrs, Conn., Agr. Expt. Station, 1899, pp. 76-79), but the factor 6.25 was used here in all cases so as to make the results more nearly comparable with those of Captain McCay.

[2] Received whole, and ground for sampling.

[3] McCay: *Loc. cit.*, pp. 34 and 35.

[4] The values for these food materials were taken from *Bull.* 28 of the Office of Exp. Sta., U. S. Dept. Agr. (1902), and represent the average of a large number of analyses.

The samples sent to the Nutrition Laboratory for analysis were taken from the old crop and packed for shipment during the hot, dry season. Captain McCay also analyzed samples of these food materials from the same crop, but the samples were selected earlier in the year when the crop first came upon the market. The results are as yet unpublished but Captain McCay reports that his analyses agree very satisfactorily with those made by us, allowing for the variations in moisture content occasioned by the difference in time of sampling.

Of special interest in the results here shown is the large amount of fat in the wheat ata. The proportion of fat in wheat flour, as commonly used in this country and as shown by some 200 analyses,[1] is from 0.3 to 1.9 per cent., while for the two samples of wheat ata analyzed by us, it was 3.39 and 2.14 per cent. respectively, and 2.90 per cent. as shown by the Calcutta analyses given in the table. The higher percentage of fat will result in a corresponding increase in the heat of combustion. The proportion of fat in the Gram dhall is also high as compared with the other varieties of dhall, being fully three times that shown for any of the others, and the heats of combustion are likewise higher.

AN APPLICATION OF THE FOLIN METHOD TO THE DETERMINATION OF THE AMMONIACAL NITROGEN IN MEAT.

BY M. E. PENNINGTON AND A. D. GREENLEE.

Received January 27, 1910.

The quantity of loosely bound nitrogen which occurs in protein-rich tissues such as meat has long been recognized as an indication of the freshness of the substance. Bacteria have been recognized as energetic agents in the decomposition of these protein-rich tissues, with the formation of relatively large amounts of such loosely bound nitrogen.

The methods for the estimation of the quantity of this nitrogen have been far from satisfactory, though the Folin method has served well for its estimation in such substances as urine.

For the estimation of the so-called ammoniacal nitrogen in meat and meat extracts, distillation with magnesium oxide has been the method most used.[2] This method, however, is unsatisfactory in that, even after hours of distillation, small quantities of ammoniacal nitrogen continue to be evolved and the conditions of the experiment, especially the rate of distillation, markedly affect the amount of nitrogen split off. That which is evolved during the first hour, when the rate is 200 cc. of distillate, is usually considerably greater than during subsequent hours, though the succeeding periods—even to the fifth or sixth—yield quantities too large to be disregarded. Such being the case, it would seem probable that the boiling with even a mild alkali causes a progressive splitting of more firmly bound nitrogen compounds that would tend to vitiate the results, because the separation of amine or other forms of nitrogen is apparently gradual rather than sharply marked.

[2] Richardson, THIS JOURNAL, 30, 1515.

Richardson gives successive distillations, up to ten, on hashed frozen meat—presumably beef—showing that approximately one-third of the total nitrogen obtained is evolved in the first hour, and that after the sixth hour the quantities vary from 0.005 to 0.002 per cent. At no time did he get nitrogen-free distillates. For practical purposes he distils but one hour.

The following table indicates the rate of the evolution of nitrogen by the magnesium oxide distillation method, using 25 grams of chicken meat, 10 grams of magnesium oxide and 450 cc. of water, and distilling at such speed that 200 cc. of distillate collect in one hour. 0.1 *N* sulphuric acid is used to collect the free ammonia.

From the foregoing determination of ammoniacal nitrogen in the flesh of chickens of varying history it would appear that it gives even less satisfactory results by distillation with magnesium oxide than does beef.

Because the determination of this loosely bound nitrogen should be one of the best methods we have for the detection of deterioration in flesh, there has been an endeavor to adapt the method of Folin to such substances, believing that in the cold and with a weak alkali, such as magnesium oxide, there would be a better chance of a sharp separation of ammoniacal nitrogen.

A study of the literature pertaining to the Folin method has shown a scarcity of detail concerning the time required and the strength of the air current. Folin in his original paper[1] states that for urine analysis 600–700 liters of air per hour are required during a period of 1 to 1$^1/_2$ hours. Boussingault in 1850[2] used 56 liters of air per hour for five hours, and found that nitrogen remained. He, therefore, abandoned the method.

Most of the more recent papers, as those of Kober,[3] Gill and Grindley,[4] and Sebellen, Brymeldsen and Haavardsholm,[5] deal with the conditions necessary for the extraction of the ammonium salts from the Kjeldahl digestion rather than from the original tissue or extract.

It seemed desirable, therefore, to attempt the elimination of loosely bound nitrogen from such substances as meat and its extracts by a strong current of air, and to observe the results between the volume of air and the time required for the doing of the work. It has been found that the usual water pump of the laboratory is not adequate. A small air pump, driven by a $^1/_4$ h. p. motor, answers the purpose, and an anemometer, such as is used to measure the volume of air entering mine shafts, etc., records the total volume of air passing through the apparatus. The ingoing air is purified by sulphuric acid in a flask provided with a Hopkins safety bulb. It then passes through a liter flask in which 25 grams of finely-ground meat are suspended in 250 cc. of water, with 5 grams of magnesium oxide. Between this flask and the 0.1 *N* sulphuric acid absorption bottle is an empty 250 cc. flask, to catch any mechanical spattering or frothing; and beyond the acid bottle a 100 cc. flask is placed to catch any particles of the acid that may pass into the exit tube. The flasks are set up in batteries of four, using one brass or glass four-way tube to connect with the air pump, and another of similar form leading to the air wash bottle (see figure on next page).

It has been found that about 30,000 cubic feet of air through the whole system or 8,000 cubic feet through each individual series of flasks, and a period of three to six hours, is sufficient to remove all of the nitrogen which is eliminated by weak alkali at an ordinary temperature When such an

elimination has occurred the receiving flasks remain free from ammoniacal nitrogen even though a rapid current of air be passed for several additional hours.

The addition of about 25 cc. of alcohol largely prevents the foaming of the protein, which may happen during the latter part of the aspiration period. When once started but little attention is required except an occasional shaking of the flasks. One gram of sodium fluoride, and a temperature of 10–15°, has been found a satisfactory method of preserving unchanged the suspension of meat in water for a period of 24 hours — a fact which is of considerable importance, if many samples are received at one time.

Like the evolution by distillation with magnesium oxide, the preponderance of ammonia is given off during the first hour but, unlike that procedure, there is a steady decrease until the zero point is reached. Table II illustrates the rate of evolution as influenced by the time and the amount of air.

In certain experiments sodium carbonate was used as a hydrolyzing alkali in quantities varying from 0.5 of a gram to 2 grams, side by side with magnesium oxide. It is of interest to note that the evolution of

ammoniacal nitrogen was the same with both reagents. Such findings may be taken as evidence of the sharply differentiated linkage of loosely bound nitrogen in protein, which is certainly increased during bacterial decomposition and probably during enzyme decomposition (Table III).

A patient endeavor has been made in this laboratory to correlate the ammoniacal nitrogen evolved by the magnesium oxide distillation method with the condition of preservation of the chicken meat. While variations in the amount were visible when wide differences in the flesh were apparent to the sense of sight, odor, etc., small differences for which laboratory data were essential were more frequently confused than clarified by the analytical results.

Though the quantity of nitrogen obtained by air aspiration is always considerably less than is given off in the first hour by distillation, duplicate analyses check closely and individual samples having the same history show similar amounts of nitrogen with a gratifying regularity. Table IV illustrates this point and indicates, also, the variations by the distillation method when examining samples from the same source.

The results tabulated are divided into three groups—(*a*) chickens chilled in dry air at 0° for 24 hours after killing, which is sufficient to completely remove the animal heat; (*b*) chickens of known history preserved in a refrigerator having a temperature of 10–15° for varying numbers of days; (*c*) chickens, generally of known history, preserved hard frozen for varying periods of time.

It will be noted that the perfectly fresh birds show 0.011 to 0.012 per cent. of ammoniacal nitrogen in the tissue; those kept at moderately low temperatures for from 4 to 9 days run from 0.014 to 0.019 per cent.; while cold-stored specimens all more than a year old, show a wide variation in the quantities depending on their condition, but always much higher than the fresh. The ammoniacal nitrogen obtained from the aqueous extract of the tissue is generally a little less than from the tissue itself.

[CONTRIBUTION FROM THE FOOD RESEARCH LABORATORY, BUREAU OF CHEMISTRY, UNITED STATES DEPARTMENT OF AGRICULTURE.]

THE DETERMINATION OF THE ACID VALUE OF CRUDE FAT AND ITS APPLICATION IN THE DETECTION OF AGED FOODS.

BY M E PENNINGTON AND J S HEPBURN.

Received March 3, 1910

During the study of the handling of poultry intended for food, at present under way in this laboratory, it has been found necessary to devise methods for a more accurate estimation of changes in the composition of flesh than have been in common use and which would be sufficiently prompt to permit of the testing of a larger number of samples each day than is ordinarily accomplished with a moderate laboratory force. The acidity of the fat of the chicken has been found to be a sensitive index of the state of preservation of the whole bird. It increases from a very low value in the freshly killed specimen to forty or fifty times the original number, according to the method of preservation and the length of the keeping period. However, the usual procedure for the estimation of the amount of free acid in the fat, that is, extraction with a suitable solvent, drying, etc., was so time-consuming that its use was greatly restricted. It seemed desirable, therefore, to so modify the method that accurate results could be obtained without such an expenditure of time.

It is a common practice in packing-house work to render by a low heat beef or mutton fat and store for commercial purposes. The acid value of such a rendered fat is determined directly in hot alcoholic solution. The rendering of crude fat as a preparation for analysis is mentioned by Dieterich[1] and Pastrovich[2] studying the autohydrolysis of raw tallow rendered it on the water bath with the addition of a few drops of sulphuric acid to decompose the ammonium soaps which had formed in the decomposition. Several washings with hot water freed the fat from excess of mineral acid and it was then dried, weighed, and its acidity determined.

Rendering a fat to free it from enclosing membranes must be carefully done else the heat will cause a splitting, and oxidation must also be considered.

A determination of the amount of water present in the gizzard fat or subcutaneous fat of chickens shows but 5 per cent., or less. This quantity of water, when samples of 10 grams are taken for the determination of the acidity, can be disregarded. The supporting membranes are also a negligible quantity. Accordingly, the fat, both that from the gizzard and from beneath the skin, separated mechanically is ground in a meat chopper and weighed directly into a 250 cc. Erlenmeyer flask. To this is added 50 cc of alcohol which is neutral to phenolphthalein. This dye is then added as an indicator and the whole brought to brisk boiling, preferably on an electric stove which gives an even heat. The hot alcohol dissolves the fat. It is titrated immediately with 0.1 *N* sodium hydroxide, shaking vigorously, until a pink color appears. The color is not permanent. Indeed it fades very rapidly; hence, a color persisting for one-fourth of a minute can be taken as the end reaction. From the amount of sodium hydroxide used the acid value can be calculated or, if the result is to be expressed as free oleic acid, the latter is found by multiplying the acid value by the factor 0.503.

A simultaneous determination of the acidity of the fat by this method and by extraction with petroleum ether according to the official method of the Association of the Official Agricultural Chemists,[3] as modified by this laboratory, namely, using heat with the solvent to ensure thorough extraction,[4] has been made on fat from chickens kept for varying lengths of time after slaughter and from which the animal heat had been removed both by cold air and by water and ice. The acid value has been determined, also, for both gizzard and subcutaneous fat. The results are collected in Table I.

It will be observed that the acidity of the crude fat of a chicken chilled in dry air at about 0° C. for 24 hours after slaughter is less than one—generally 0.8, or, reckoned as oleic acid, 0.40 per cent. A comparison of the values obtained from the same fat after extraction shows either absolute agreement or a close duplication so long as the fat has not aged.

When the fat ages the acidity of the crude material is frequently higher than when extracted by petroleum ether. In a few cases the crude fat has been found to give a lower figure than the extracted. Be the comparative values higher or lower, agreement is uncommon, as is indicated in the latter part of Table I.

In the fresh chicken the acid value of the gizzard fat is generally a little less than that of the subcutaneous fat. It may occasionally be very slightly higher. Even so, the acidity of the fat from the two sources is, in the fresh condition, nearly the same.

As the fat ages, it increases in acidity, whether at a temperature below the freezing point, at the temperature of the usual packing-house chill room or the housewife's refrigerator. This increase is pronounced long before the usual signs of deterioration become manifest and for that reason it is of value as a gauge of incipient decomposition.

Table II shows the acid value of the crude fat of fowls of varied history. In a number of cases several analyses have been made of the same lot of fowls at different periods. These experiments show a progressive increase in the acid value as the time lengthens, and they also show that the more perfect the prompt removal of the animal heat, the lower the acidity. The figures are also sufficiently delicate to show the difference between birds dry-air-chilled, and chilled with water and ice, all other conditions being the same. This fact is of service in determining the best methods for the handling of poultry intended for food and is being used in the examination of market poultry dressed and transported and stored in various ways.

It has been stated that in the fresh chickens the subcutaneous fat tends toward a slightly higher acidity than does that of the gizzard. In the aging chicken, on the contrary, the visceral fat is distinctly more acid and is a better indicator of the condition of the rest of the bird.

Conclusions.

The acidity of the crude fat of chickens is an excellent indicator of their freshness. The results obtained on the crude material are more reliable than after extraction with fat solvents. The acidity of the visceral fat increases with length of keeping time or bad handling more markedly than does the subcutaneous fat.

NEW BOOKS.

The Fundamental Principles of Chemistry. *An Introduction to All Textbooks of Chemistry.* By WILHELM OSTWALD. Authorized translation by HARRY W. MORSE. 341 pp. Longmans, Green & Co. Price, $2.25.

This book is a departure from conventional standards, but readers who are familiar with the author's writings will recognize that it is a natural development of ideas which he has long been known to hold. A chemistry has been worked out "in the form of a rational scientific system without bringing in the properties of individual substances." The fundamental concepts and principles of the science are presented in a logical order and "as free as possible from irrelevant additions." The author considers that the development of the methodical side of chemistry has been greatly retarded on account of the fundamental error of using hypothetical assumptions as an aid to experimental work. The end sought "is the discovery of final truths and the relations between them,—. This does not mean the setting up of analogies and hypotheses, but the careful analysis of concepts and indication of the general facts of experience from which they are derived."

The selection of material and the order in which it is presented is shown by the following list of chapters:

I. Bodies, substances, and properties. II. The three states. III. Mixtures, solutions, and pure substances. IV. Change of state and equilibrium. The equilibria (*a*) liquid-gas, (*b*) solid liquid, (*c*) between the three states, and (*d*) solid-solid. V Solutions. VI. Elements and compounds. VII. The law of combining weights. VIII. Colligative properties. IX. Reaction velocity and equilibrium. X. Isomerism. XI. The ions.

A striking feature of the book is the simple and successful development at a very early stage of the phase rule and of methods of graphical representation. One-component systems are treated in a comprehensive manner in Chapter IV, and a more general conception of the phase rule is given in V in connection with two-component systems. In Chapter VI there is presented a new method of representing in a line diagram the composition of a two-component system at constant temperature and pressure. When composition is plotted in a horizontal direction, the field of existence of each phase may be represented by a single horizontal line. Gas, liquid, and solid phases are distinguished by using dotted lines, ordinary lines, and heavy lines, respectively. The overlapping of two lines represents the co-existence of two phases.

The treatment of chemical processes in the narrower sense, and the definition of elements are dealt with in Chapter VI, and are introduced by a discussion of hylotropy and the methods of identifying a pure substance. The value of the phase relations in deciding whether a compound is formed in a binary system is determined by making a systematic classification of all possible combinations of phases, and of the new combinations obtained when a compound is formed. In this chapter, also, a proof is given of the law of constant proportions with which two substances (elements or compounds) combine to form a compound pure substance; and upon this law is based (Chapter VII) the law of combining weights, and the proof of the law of rational multiples.

In a book of this nature it is not to be expected that the readers will in all cases agree with the author's method of treatment. Many will object to the tacit treatment of the atomic theory as an "irrelevant addition" to chemistry. Some may question the validity of the "law of nature" relating to the formation of metastable substances (page 92): "Those forms appear first which are more stable than the form just left, but which are the least stable among all the possible stable forms."

It is evident at once, from the nature and scope of the book, that the sub-title is somewhat misleading. The author, however, does not expect this book to be used by a beginner. He is in fact "quite of the opinion that a close personal acquaintance with a considerable number of important and characteristic substances is and always must be the fundament of all instruction in Chemistry."

This book will be of great value to the teacher, and to every chemist who has attempted to examine for himself the basis of laws and theories frequently accepted as established or self-evident. W. C. BRAY.

Elementary Modern Chemistry. By WILHELM OSTWALD, Emeritus Professor of Chemistry in the University of Leipzig and HARRY W MORSE, Instructor in Physics in Harvard University. x + 291 pages. Ginn & Company. Price, $1 00.

A text-book in elementary chemistry written by a former professor of chemistry in one of the great German universities in collaboration with an instructor in physics in one of the great American universities would naturally command the attention of those engaged in teaching this subject. While there is a general belief, perhaps more or less unwarranted, that it is a difficult undertaking for one not engaged in teaching chemistry under the conditions which exist in secondary schools to write a text on that subject, nevertheless it is always of great interest to learn the views of others, especially of one whose achievements in chemistry have gained for him the Nobel prize. The nature of Ostwald's "die Schule der Chemie" published in 1903 would naturally lead one to believe that his ideas upon the methods of teaching elementary chemistry were entirely different from the methods in general use in the United States. In Ostwald and Morse's text, however, no such extremely radical difference from prevailing methods is to be found. In general the book not only looks, but for the most part reads, like many of the well known modern texts on elementary chemistry. Since one of the authors is a physical chemist and the other an instructor in physics, naturally the subject is approached from a physico-chemical standpoint. For example, the subject of "phases" is introduced in the first chapter (page 5) and is followed in the text by other physico-chemical conceptions. Accordingly one looks in vain for any mention of such old and familiar terms as "physical" and "chemical changes." Even the term "valence" is conspicuous by its absence.

As was to be expected the subject is presented in an attractive form. While the text proper contains only 278 pages, printed in large type and including nearly 200 experiments and one hundred figures, it contains a fairly comprehensive discussion of such fundamentals of chemistry as the average student can grasp. More attention is devoted to the general laws and less to the application of chemical processes than is generally customary in an elementary text. The book would be of little value except when used under the direction of a competent teacher well versed in the modern conceptions of chemistry. With such a person as a teacher it should prove an acceptable one for students who expect to continue the subject. WILLIAM MCPHERSON.

Recent Advances in Physical and Inorganic Chemistry. By A. W. STEWART, D.Sc., with an Introduction by SIR WILLIAM RAMSAY, K.C.B., F.R.S. With diagrams. Longmans, Green, and Co., 1909. Price, $2.50.

The book contains chapters of a dozen pages or so on some hydroxylamine derivatives (nitroxyl), reactions in liquid ammonia (Franklin's work), the fixation of nitrogen (production of nitrogen oxides, amines, cyanides, nitrides), colloids, elements of the rare earths (with a discussion of their position in the periodic system), and the inactive gases (including a history of their discovery).

More space—from thirty to fifty pages each—is devoted to cobalt-ammines, absorption spectra, atomic weights, double salts and the oceanic salt deposits, and radioactivity.

The essays are interesting and well written, and the author does not hesitate to express his own opinions when occasions arise. He stands for purposive research, not that of "investigators who photograph spectra apparently with no idea beyond finding out what the absorption curve looks like," or that of the organic chemists who "apply somebody else's reaction to the iso propyl derivative when the lower members of the series have already been made." Theories, he thinks, should be capable of being tested, and not "mere verbiage and an excuse for dodging round a dialectic corner as soon as people begin to look into the subject."

The book might well find a place in the reading prescribed for advanced students of chemistry; its one weak point seems to be the chapter on Double Salts, which needs very careful revision. W. LASH MILLER.

OF THE

American Chemical Society

ON THE OXALATES OF HYDRAZINE.

By J. W. TURRENTINE.

Received March 3, 1910

In 1889[1] Curtius made mention of the formation of an oxalate of hydrazine obtainable by heating triazoacetic acid with a saturated, aqueous solution of oxalic acid. The product was described as a substance crystallizing in small, glistening plates, soluble in water. No attempt was apparently made to ascertain whether the substance was a monoxalate or a dioxalate of hydrazine, and no analytical data whatever were published.

The purpose of the present investigation has been the preparation and study of the two oxalates of hydrazine, $(N_2H_4)_2H_2C_2O_4$ and $N_2H_4.H_2C_2O_4$. It has been thought possible, moreover, that the decomposition of these substances, especially in view of a probable ring structure of the dioxalate, might yield some interesting results.

Hydrazine Monoxalate.

Method of Preparation.—An aqueous solution of this substance was prepared by treating 10 cc. of a 73 per cent. solution of hydrazine hydrate, with 9.18 grams of oxalic acid dissolved in a small amount of water. The solution was filtered and after evaporation on the water bath to the point of saturation was allowed to cool, with the result that a large quantity of minute crystals was obtained. The crystals were first drained on filter paper and were then dried to constant weight in a desiccator over calcium chloride.

Method of Analysis.—Weighed samples of the dried crystals were dissolved in water and the solutions were made strongly alkaline with ammonium hydroxide. They were then heated to boiling and an excess of a solution of calcium chloride, containing 25 grams per liter, was added slowly and with constant stirring. After the precipitates had been allowed to subside, they were filtered and were thoroughly washed with hot water.

---

[1] Curtius and Jay, *J. prakt Chem.*, 39, 27–59 (1889).

In order to avoid the error arising from the possible presence of calcium carbonate in the calcium oxalate thrown down by this method, the precipitates were dissolved in hot, dilute sulphuric acid, and the oxalic acid was determined by titration with a standard solution of potassium permanganate.

The results obtained in four determinations indicate the ratio, mols. N_2H_4 : mols. $H_2C_2O_4$ to be (1) 2 : 1.02; (2) 2 : 1.00; (3) 2 : 0.99; (4) 2 : 0.99. Theory, 2 : 1.00. The average of these results, calculated to a percentage basis, is as follows $H_2C_2O_4$ found, 58.60 per cent.; theory for $(N_2H_4)_2.H_2C_2O_4$, 58.44 per cent.

Three analyses of the monoxalate by the permanganate method described in detail in a subsequent paragraph show the ratio, mols. N_2H_4 : mols. $H_2C_2O_4$ to be (1) 2 : 0.99; (2) 2 : 0.98; (3) 2 : 1.00. Theory, 2 : 1.00. The average of the three results, calculated to percentage of N_2H_4, gave N_2H_4 found, 41.45 per cent. Theory, 41.59 per cent.

Properties.—Hydrazine monoxalate is a white substance that crystallizes from aqueous solution in the form of very fine needles and plates. When the attempt is made to recrystallize the compound, an amorphous substance is frequently obtained in the form of a jelly, which, on evaporation, becomes hard and opaque.

The monoxalate is extremely soluble in water, as shown by the results obtained in the following series of solubility determinations made at 35°. One gram of water at this temperature was found to dissolve (1) 2.003, (2) 1.998, and (3) 2.018 grams, or an average of 2.009 grams of the salt.

Three determinations of the solubility of this compound in absolute alcohol at a temperature of 21.9° showed that it was practically insoluble, or that 1 cc. of alcohol dissolved about 0.0003 gram. The substance is also insoluble in ether. No appreciable residue was left after the evaporation of a small portion of ether that had been shaken with the salt at intervals for several hours. In the case of both alcohol and ether, the liquid was heated to its boiling point in the presence of the salt, and was allowed to come to constant temperature, with frequent shaking, in a thermostat.

No definite melting point is shown by the monoxalate, which in this respect is similar to many other hydrazine compounds. At a temperature of 130° (±2°) it begins to decompose, although even at lower temperatures some indication of incipient fusion is obtained. Above this temperature the compound is eventually transformed into a clear liquid, whether the substance be heated in an open or in a closed capillary tube.

When this liquid is allowed to cool it solidifies, yielding a product that melts at 150° (±2°).

Decomposition.—The decomposition of hydrazine monoxalate was studied under four different sets of conditions, as follows: (1) On a platinum plate in the open air; (2) in an open glass tube; (3) in an atmosphere of hydrogen; (4) *in vacuo*, with a view to the analysis of the evolved gases.

(1) When crystals of the monoxalate were heated on a platinum plate in the open air they fused and boiled, assuming a yellow color. This color gradually deepened to a brown and finally to a black, as the charring of the substance progressed. Throughout the decomposition there was a visible evolution of fumes. Whenever the rate of heating was sufficiently rapid the substance took fire and burned with a blue flame of carbon monoxide.

(2) This experiment was performed in order that the fumes noted in Exp. 1 might be partially condensed and examined. A portion of the substance which had been dried to constant weigh' at a temperature of 100–5° was gradually decomposed. by heating, in an open glass tube. Essentially the same phenomena were observed to take place in the same sequence as in Exp. 1. The vapor which escaped from the tube, as well as that which condensed on the walls, gave a distinct alkaline reaction to red litmus and emitted the odor of hydrazine hydrate. Later in the decomposition the odor of a cyanide was detected, and before the presence of that substance was suspected, symptoms of cyanide poisoning were experienced.

(3) A third experiment was designed with a view to the collection of decomposition products absorbed in acid or in alkaline solution. The decomposition was effected in an apparatus consisting of a glass distilling flask, provided, in lieu of a stopper, with a glass tube sealed in the neck, and extending perpendicularly nearly to the bottom. The side arm of the flask was fused to a Muencke gas wash bottle, containing dilute sulphuric acid. A similar bottle connected to the first and contained carbon-dioxide-free potassium hydroxide.

A stream of hydrogen, purified with the aid of alkaline permanganate, soda lime, and concentrated sulphuric acid, was employed in sweeping the uncondensed products of decomposition into the gas wash bottles.

About one gram of the oxalate was placed in the flask and the air in the entire apparatus was displaced by hydrogen. The compound was then slowly heated to decomposition. At the end of the experiment a small amount of carbon remained in the flask.

An appreciable amount of ammonia and a small quantity of hydrazine were found in the first wash bottle. The alkaline solution in the second bottle was found to contain a small amount of carbonic acid and a considerable quantity of hydrocyanic acid, as shown by both the Prussian blue and the sulphocyanate tests.

During the early stages of the decomposition a liquid condensed on the walls of the neck and side arm of the flask. In Exp. 2 this liquid was shown to be in part, at least, hydrazine hydrate. Two drops of the condensate were subjected to analysis for hydrazine by the method of Rimini.[1] The results obtained when calculated to hydrazine hydrate gave a concentration of 9 per cent. It is probable, however, that the liquid contained in solution compounds of hydrazine other than the hydrate.

The most conspicuous of the substances produced by the destructive distillation of the monoxalate was a white crystalline sublimate deposited on the cooler parts of the flask and of the decomposing substance itself. When a drop of the aqueous solution of this sublimate was evaporated under the microscope, glistening needle-shaped crystals separated out. These crystals were found to contain no carbonic, hydrocyanic, or oxalic acid, and were shown to be capable of reducing acidified potassium iodate in the cold. When the solution from which the hydrazine had been removed by oxidation was subjected to the microchemical test for ammonia with chloroplatinic acid, negative results were obtained. When heated on a platinum plate the substance decomposed, leaving a residue of carbon, thus indicating the presence of organic matter

(4) The decomposition was effected under such conditions that all gaseous products unabsorbable by sulphuric acid or potassium hydroxide could be collected for analysis, uncontaminated by air. The apparatus employed in this experiment was constructed as follows:

To the capillary tip of a Hempel gas burette was joined, by means of a short section of rubber tubing, a Y-tube, one arm of which was closed by a piece of narrow-bore rubber tubing provided with a screw clamp and a tightly fitting glass plug. To the other arm was sealed a glass stop-cock. A section of glass tubing, 0 5 cm. internal diameter and 19 cm long, designed as the container for the substance which was to undergo decomposition, was closed at one end and was sealed to the tube bearing the glass stop-cock. It was then bent so as to extend horizontally outward and in a plane perpendicular to that occupied by the glass Y. It was necessary, of course, in each case to place the compound which was being studied in the tube designed as its receptacle before the fused joint was effected. The burette was filled with mercury. By alternate raising and lowering the level tube of the burette and by suitable manipulation of the valves of the Y-tube, the pressure in the tube containing the sample was reduced to less than 1 mm.

A sample of the hydrazine monoxalate weighing 0.2128 gram yielded about 35 cc. of gas when decomposed in the apparatus just described.

---

[1] Rimini, *Gaz. chim. ital.*, **29**, I, 265–9 (1899); *Chem Zentr.*, **1899**, II, 455.

Of this gas, a volume of 25.8 cc. was passed successively into Hempel pipettes containing potassium hydroxide, alkaline pyrogallol, and ammoniacal cuprous chloride. The contraction observed in the first case was 3.0 cc., corresponding to 11.6 per cent. of gases absorbable in potassium hydroxide. Only a trace of oxygen was found. The contraction noted after treatment with ammoniacal cuprous chloride was 4.5 cc., corresponding to 17.4 per cent. of carbon monoxide.

The residue, 18.3 cc. in volume, was non-inflammable, and was therefore taken as nitrogen; this volume represented 70.9 per cent. of the whole.

A summary of the results of the above experiments shows that the monoxalate of hydrazine is quite unstable at moderately high temperatures and on decomposing yields water, ammonia, hydrocyanic acid, probably in combination, hydrazine, carbon dioxide, carbon monoxide free nitrogen and carbon. An unidentified and more complex compound of hydrazine is found and appears as a white, crystalline sublimate. This compound is being subjected to further investigation.

Hydrazine Dioxalate.

Method of Preparation.—The dioxalate of hydrazine was prepared by adding, drop by drop, to a hot, concentrated solution of oxalic acid, containing 11.02 grams $H_2C_2O_4$ $2H_2O$, 6 0 cc. of a 73 per cent. solution of hydrazine hydrate containing 4 4 grams $N_2H_4.H_2O$. Before the last of the hydrate had been added to the solution of the acid, brilliant crystalline flakes began to appear. The solution was heated, with stirring, until these had redissolved. Then, on cooling, a large mass of beautiful, glistening crystals was obtained. These were filtered by suction, were washed rapidly in cold, distilled water, also with the aid of suction, and were then dried in the open air.

Analysis.—Three samples of this compound, previously dried in an air bath for one-half hour at a temperature of 100–8°, were analyzed for oxalic acid by the calcium chloride precipitation method, outlined above under the analysis of the monoxalate.

The result obtained in three determinations showed the ratio between the molecules of hydrazine and oxalic acid to be (1) 1 : 1.00; (2) 1 : 1.01; (3) 1 : 0.98; theory, 1 : 1. When calculated to a percentage basis the average of these results is: $H_2C_2O_4$ found, 73.63 per cent.; theory, calculated for $N_2H_4.H_2C_2O_4$, 73.60 per cent.

The principal methods so far proposed for the determination of the hydrazine radical in compounds of that substance involve reactions in which that radical undergoes oxidation. Rimini[1] prescribed the use of potassium iodate in acid solution, adding a measured excess of the iodate and titrating the excess with thiosulphate, after reduction with potassium iodide. Petersen[1] employed potassium permanganate in acid solution, as did also Roberto and Roncali,[2] while Sebanejeff[3] used the same oxidizing agent in alkaline solution. He determined the hydrazine radical in an inorganic salt by adding an excess of that reagent and titrating back with arsenious acid.

---

[1] Rimini, *Loc. cit.*

These methods do not lend themselves readily to the analysis of the oxalates of hydrazine on account of the peculiar fact that both the basic and the acid radicals in this compound are strong reducing agents and both react with the oxidizing substances prescribed. This consideration debars the use of the methods of Rimini, of Petersen and of Roberto and Roncali. The use of permanganate in alkaline solution as outlined by Sebanejeff might be employed with modification, as permanganate is not reduced by oxalic acid in alkaline solution, but this procedure would involve a tedious titration with arsenious acid. To acidify the solution for this titration would result in the immediate reduction of the excess of permanganate by the oxalic acid. In the alkaline solution which is therefore required, a voluminous precipitate of manganese compound forms which must be allowed to settle before any color change can be detected in the solution. Moreover, the presence of oxalic acid might interfere in the titration by reducing the arsenic acid[4] then formed, though it is doubtful whether this reduction could occur in an alkaline solution.[5]

These considerations made it necessary to devise a method of analysis which would take into account the reducing action of both radicals of the oxalates and which would therefore permit the simultaneous determination of both hydrazine and oxalic acid. The method of Rimini, which is the most satisfactory for the determination of hydrazine, could not be adapted to this purpose, for while potassium iodate oxidizes oxalic acid, the reaction is too slow,[6] even in hot acid solution, to admit of titration. Potassium permanganate, it has been shown by Browne and Shetterly in their studies on the oxidation of hydrazine,[7] does not oxidize hydrazine in acid solution quantitatively to nitrogen and water, but yields varying amounts of hydronitric acid and ammonia. Methods based on the use of this reagent in acid solution are therefore unreliable. Likewise, in alkaline solution, if the permanganate be added slowly, small amounts of these products are formed. On the contrary, if an excess of the permanganate is added at once in alkaline solution, the amounts of hydronitric acid and ammonia formed are negligible.[1]

[7] Browne and Shetterly, THIS JOURNAL, 31, 221 (1909).

In the light of these facts a method of analysis was devised in which the hydrazine was oxidized by permanganate in alkaline solution, and the oxalic acid by more permanganate in the same solution after acidification.

Essentially the following procedure was adopted: The sample to be analyzed was dissolved in water in an Erlenmeyer flask and was treated with 10 cc. of a 4 *N* solution of sodium hydroxide. An amount of standard permanganate solution sufficient to oxidize the hydrazine completely, but not enough to oxidize all of the oxalic acid, was then added and the solution was acidified by adding 5 cc. of concentrated sulphuric acid. After the solution had been warmed until the oxides of manganese had gone into the solution, a clear, colorless liquid remained. Potassium permanganate was then added, drop by drop, until the faintest possible permanent coloration was produced.

The permanganate solution employed in the analysis was standardized first against a standard solution of oxalic acid and then against a solution containing accurately known amounts of both hydrazine sulphate and oxalic acid. The procedure followed in this standardization was identical with that adopted in the analysis. By subtracting from the total volume of permanganate solution used the volume required for the complete oxidation of the oxalic acid, the volume consumed by the hydrazine present was ascertained. From these results may be calculated the value of the permanganate solution in terms either of the monoxalate or of the dioxalate. One cc. of permanganate solution employed was found to correspond to 0.00213 gram of $N_2H_4.H_2C_2O_4$.

The results of the analysis are recorded in Table I:

TABLE I.

No. of experiment.	Weight of $N_2H_4.H_2C_2O_4$	$KMnO_4$ solution used. Calculated. cc.	Found. cc.	Weight of N_2H_4 $H_2C_2O_4$ found.	Per cent N_2H_4 $H_2C_2O_4$ found

Properties.—The dioxalate of hydrazine crystallizes in glistening needles, without water of crystallization.

As compared with the monoxalate, the dioxalate of hydrazine is only sparingly soluble in water. The following procedure was followed in the to the acid solution for hydrazine with Fehling's solution yielded negative results. (*b*) The liquid condensate showed a slight alkaline reaction toward litmus and responded feebly to tests with iodate for hydrazine. On evaporation a slight residue was obtained which was identical with the white sublimate described below. Acidification caused effervescence. (*c*) The white sublimate was removed from the side arm of the distilling flask, partly in solution and partly in suspension in a small amount of water; in this solvent it was not very soluble On the evaporation of a few drops of the aqueous solution there separated out what, through the microscope, appeared to be small, amorphous particles. It was more soluble in hot water than in cold, and it also dissolved readily in dilute sulphuric acid. The solution in acid was not accompanied by any effervescence, which fact showed the absence of carbonates. Negative results were obtained from tests for cyanides and also for hydrazine by the iodate method. Ammonia was freely evolved when sodium hydroxide was added to the warm aqueous solution of the compound. When heated on the platinum plate, the substance decomposed and left a deposit of carbon, thus showing the presence of organic matter.

[1] Browne and Shetterly, *Loc. cit.*

(4) This experiment was designed to parallel as closely as possible the corresponding experiment on the decomposition of the monoxalate.

A sample of dried crystals, 0.5030 gram in weight, gave rise on decomposition to a total volume of gas of about 127 cc., of which 116.8 cc. were analyzed. When this volume of the gas was subjected to the action of the different absorbents there was a contraction in potassium hydroxide solution of 68.9 cc., corresponding to 59.1 per cent. of carbon dioxide and hydrocyanic acid or cyanogen; in alkaline pyrogallol, a slight contraction representing a trace of oxygen; and in ammoniacal cuprous chloride, a decrease in volume of 19.8 cc., corresponding to 17.0 per cent. of carbon monoxide. The residue, which occupied a volume of 27.5 cc., equal to 23.5 per cent. of the total volume, was assumed to be nitrogen.

(5) It was noticed in the melting point determination of the dioxalate that, when a sealed capillary tube was used, at a temperature of 200°, a liquid was formed which did not solidify on cooling. In order to study this decomposition more thoroughly the following procedure was adopted.

A small sample of the pure, dry dioxalate was sealed in a section of combustion tubing, from which the air had been exhausted by means of a mercury pump, and was heated in a bomb furnace for about one-half hour at a temperature varying from 200° to 210°. A certain volume of xylene was enclosed with the tube in the bomb so that the internal pressure exerted by the gases evolved during the decomposition might be equalized in part by the external pressure developed by the vapor of the xylene. When the tube was removed from the bomb the substance which it contained was found to be a clear, sirupy liquid.

On examination, the liquid as well as the vapor showed marked alkalinity toward red litmus. By means of suitable tests, cyanides were found to be absent; in Fehling's solution very small amounts of the liquid were sufficient to produce a decided reduction.

This liquid was allowed to stand for several days in a tube closed only with a cork whereupon a white crystalline solid separated out. The crystals were washed thoroughly with absolute alcohol, in which they showed only slight solubility The alcohol precipitated more crystals from the mother liquid. The crystalline substance was dissolved in water from which, on evaporation, it separated readily in glistening needles. It was found to reduce acidified potassium iodate and contained no carbonic or hydrocyanic acid. The addition of a few drops of calcium chloride solution to the aqueous, ammoniacal solution of the substance resulted in no precipitation whatever. The subsequent tests, made microchemically, with the same reagents but in a much more concentrated solution, resulted in a decided precipitation, appearing to indicate the presence of an oxalate. A quantitative determination of oxalic acid in a weighed sample was then attempted with the surprising result that when the supposed precipitate of calcium oxalate was being washed on the filter with hot water, it completely dissolved.

The results of this series of experiments show that the dioxalate, when subjected to destructive distillation in absence of air, breaks down with formation of water, ammonia, hydrocyanic acid, probably combined, carbon dioxide, carbon monoxide, nitrogen and carbon. An unidentified white compound of ammonia appears as a sublimate. The decomposition in a sealed tube leads to the formation of a substance which appears to be a hydrazine compound of a carboniferous acid. This unidentified acid, in concentrated aqueous solution, forms a calcium salt, insoluble in cold water but soluble in hot water.

On comparing the respective products of decomposition of the two oxalates, it is seen that intramolecular oxidation in the case of a dioxalate results in the almost complete destruction of the hydrazine radical, so that only minute amounts of that substance are found among the products, while, in that of the monoxalate, where the amount of acid present is only one-half as great, the oxidation is so incomplete that hydrazine is freely evolved. Also, where an ammonium compound, appearing as a sublimate, is formed from the dioxalate, from the monoxalate is produced a hydrazine compound. Both substances appear to be a salt of an acid containing carbon.

A comparison of the two substances obtained respectively from the destructive distillation of the monoxalate and the heating of the dioxalate in a sealed tube, neither as yet having been subjected to a quantitative analysis, indicate that they are closely related if not identical. This judgment is based on the similarity of their behavior toward certain reagents and when heated in melting-point tubes; neither exhibits a definite melting point, but the one duplicates closely the behavior of the other at like temperatures.

Titration of Hydrazine Dioxalate with Standard Alkali.—Salts of hydrazine, such as the dichloride[1] and the disulphate, show an acid reaction in aqueous solution.

One-half of the acid in the salts behaves as so much free acid[2] and may be titrated with alkalies. In agreement with the other diacid salts, hydrazine dioxalate is likewise acid in its reactions. Consequently attempts were made to titrate its free acid.

In previous titrations methyl orange has been employed, but on account of its lack of sensitiveness to oxalic[3] acid it could not be used in these experiments.

Curtius[4] has shown that the indicators—methyl orange, cochineal, corallin, tropeolin, fluorescein and litmus—give definite end points when used in the titration of hydrazine hydrate with 0.1 *N* H_2SO_4. He did not show, however, what the condition of the hydrazine at this end point was with respect to its combination with the acid. Cohn states that litmus and corallin are sensitive to oxalic acid. The titration of hydrazine dioxalate with azolitmin and with rosolic acid as indicators fail to give with any degree of sharpness the point of neutralization of that salt. Titrations with standard sulphuric acid with the extremely sensitive indicator, erythrosin, however, of a solution made alkaline by the addition of a definite volume of standard sodium hydroxide, gave results which indicated that the neutral point corresponds to the presence in the solution of only the monoxalate. The reaction may be represented by the following equation:

$$2N_2H_4.H_2C_2O_4 + 2NaOH = (N_2H_4)_2.H_2C_2O_4 + Na_2C_2O_4 + 2H_2O.$$

With phenolphthalein as indicator, the whole of the oxalic acid may be titrated with sodium hydroxide solution. In the case of none of the indicators tried was a sharp end point obtained.

CORNELL UNIVERSITY, September, 1909.

THE EXACT DETERMINATION OF SULPHUR IN SOLUBLE SULPHATES.

BY E. T. ALLEN AND JOHN JOHNSTON.

Received February 14, 1910.

It was in the course of an investigation of the sulphides of iron that our attention was first directed to the inaccuracy of the ordinary sulphur determination. Without going into the details of the analytical methods, it is finally necessary in all of them to precipitate the sulphur from a mixture of sulphate and chloride. The results we obtained were invariably low, and here surprisingly so, as the errors are magnified by the large percentage of sulphur in these compounds (53.4 per cent. in FeS_2). The ordinary methods, which, even in very careful work, easily involve a loss of 2 per cent. or more of the total sulphur, were inadequate for the purposes of our problem, and we were therefore forced to investigate them. The complications we encountered led us somewhat farther afield than we at first intended, though the importance of the analytical problem and some considerations of a more general nature seemed to justify this. Several sources of error were discovered, satisfactorily accounting, in the end, for all the losses. Some of these, it is true, have been noted by other observers, for the field is an old one, but nowhere in the literature has the subject been treated on a systematic, quantitative basis.

The most important of the errors are involved in the precipitation of the sulphur after it has been transformed into soluble sulphate, and to these we will confine our attention in this paper.

Richards and Parker[1] and Hulett and Duschak[2] have studied the precipitation of *sulphuric acid* by barium chloride and of barium chloride by sulphuric acid. Their work shows that the barium sulphate thrown down under these conditions always weighs too much, because it is contaminated with barium chloride which cannot be washed out; and that exact results may be obtained by determining the chlorine in the precipitate and deducting the barium chloride equivalent to it from the weight of the crude barium sulphate. This part of the subject appears to be satisfactorily settled. The little we have done on it only confirms the statements of the authors quoted.

We have devoted nearly all of our attention to the precipitation of sulphur from *soluble sulphates*—a case which occurs much more frequently in actual practice. Here the results are always low, at least this is true of the sulphates of sodium, potassium and ammonium. We will consider first the precipitation of solutions of pure sodium sulphate.

A. The Precipitation of Sodium Sulphate by Barium Chloride.

The purity of the salt we used in our work was carefully tested in the following manner:

To free it from moisture, a thin layer of the powdered salt was heated in platinum to 200–225° for an hour or more. After the heating, we found it could be melted without losing more than 0.02 per cent. of its weight. Then it was transformed into sodium chloride by the addition of a slight excess of barium chloride; the barium sulphate was filtered out and the soluble chloride in the filtrate evaporated to dryness, heated to incipient redness, and weighed. To this quantity was added a correction for a certain amount of sodium, calculated to chloride, which was carried down by the precipitate.[1]

[2] *Z. anorg. Chem.*, 40, 196 (1904).

(*a*) 1.2160 g. Na_2SO_4 gave 1.0026 g. NaCl. Calculated, 1.0008 g.
(*b*) 1.2156 g. Na_2SO_4 gave 1.0009 g. NaCl. Calculated, 1.0003 g.

Potassium was sought for by treating the total chlorides (from another portion of salt) with an equivalent quantity of chloroplatinic acid and evaporating to dryness on the steam bath. The residue was treated with successive portions of 93 per cent. alcohol till the greater part was dissolved, when the remainder was dried, a little more platinum solution added, and the procedure repeated. A little characteristic golden yellow residue was obtained.

(*a*) 0.995 g. chlorides gave 2.9 mg. K_2PtCl_6, equivalent to 0.08 per cent. K_2SO_4 in the original salt.

(*b*) 0.997 g. chlorides gave 3.3 mg. K_2PtCl_6, equivalent to 0.09 per cent. K_2SO_4.

The precipitated barium sulphate was also examined for potassium, but none was found in it. This quantity of another sulphate is, of course, too small to make any appreciable difference in the weight of our barium sulphate precipitates. The only other impurity noted in the sodium sulphate was a trace of iron.

Method of Precipitation.—The sulphate, dried as previously described, was, in some cases, weighed directly, but in general, to avoid exposing the anhydrous substance frequently to the air, a given quantity of salt was made up to a given weight of solution and weighed portions of this were taken for individual determinations.

About 24.35 grams dried sodium sulphate, weighed carefully to the milligram, was put into a tared flask and diluted till the solution weighed about 1000 grams. The weight was determined to the nearest centigram. Portions of this solution of about 50 grams were then weighed to the milligram in a weight burette, making all necessary corrections for the buoyancy of the air. This was then diluted in a Jena glass beaker to 350 cc. with hot water, acidified with a measured quantity of hydrochloric acid, heated to boiling, and precipitated by a slight excess of 10 per cent. solution of barium chloride (*i. e.*, a solution containing 100 grams $BaCl_2.2H_2O$ in 1 l.). Two grams $BaSO_4$ requires 20.9 cc. 10 per cent. $BaCl_2$ solution; while we used 22–22.5 cc.[2] The reagent was let into the sulphate solution from a burette, either drop by drop, or, better, in a thin stream which flowed down the side of the beaker.

---

[1] The method of this correction will be described later (page 594).

[2] A greater excess was shown to exert no appreciable influence on the results (see p. 597).

The precipitates were commonly allowed to stand for about 18 hours, filtered on paper, and thoroughly washed till the filtrate showed only the merest opalescence with silver nitrate;[1] this required 1 to $1^1/_2$ hours' washing with precipitates of 2 grams. The moist precipitate and filter are then burned *very slowly and carefully* in a platinum crucible. The filter must not be allowed to take fire, for in spite of some statements to the contrary, we find the sulphate is readily reduced and not easy to oxidize completely, once reduction has taken place—at least this is true of large precipitates. As soon as the filter is entirely burned, the crucible cover is moved to one side to admit the air, the temperature raised and the heating continued till the weight is constant. Once the paper is burned, a further heating of 20 minutes will very nearly suffice.

Gooch crucibles were also tried They obviate all danger of reduction, of course, and are well adapted to small precipitates; but large precipitates are inclined to clog the filter and demand much time in washing. For this reason the results are likely to be somewhat high when Gooch crucibles are used.

The precipitates prepared as described weighed about 2 grams each. We chose this quantity for two reasons: first, it is about the quantity of barium sulphate yielded by 0.5 gram of iron pyrites; and second, and more important, it is a quantity sufficiently large to trace the small percentage errors with some degree of certainty.

Determinations of the sulphur in pure sodium sulphate carried out in this manner are always too low, the deficit varying with the conditions from 0.3 per cent. to 0.5 per cent., and sometimes even more. We will now take up these errors in order.

1. Loss Due to "Solubility."[2]—This is the most obvious source of error, and though the least important, unless the precipitate is quite small, it is much increased by free acid. We have determined it in the usual way by evaporating the filtrate and washings to dryness in a platinum basin, adding a little water to the residue, and filtering on a very small ashless paper. Great pains were taken to remove any adhering film from the dish, to avoid loss of any material by running through the filter, and to wash the precipitate completely. Table I shows the losses from solubility. It will be noted that these increase with the concentration of acid in the original solution, and therefore that the less acid one chooses, the better, so far as this loss is concerned. Later, it will apof a slight excess of barium chloride; the barium sulphate was filtered out and the soluble chloride in the filtrate evaporated to dryness, heated to incipient redness, and weighed. To this quantity was added a correction for a certain amount of sodium, calculated to chloride, which was carried down by the precipitate.[1]

---

[1] A test with a very dilute standard solution showed the chlorine at this stage to be equal to about 0.005 mg. in 25 cc. of the washings.

[2] These losses are not in every case to be referred entirely to the solubility of barium sulphate in the supernatant liquid; but may be in some cases partly due to the well-known tendency of barium sulphate to creep. Hence the figures given in the table are to be taken, not as quantitative measurements of this solubility, but as analytical corrections.

(*a*) 1.2160 g. Na_2SO_4 gave 1.0026 g. NaCl. Calculated, 1.0008 g.
(*b*) 1.2156 g. Na_2SO_4 gave 1.0009 g. NaCl. Calculated, 1.0003 g.

Potassium was sought for by treating the total chlorides (from another portion of salt) with an equivalent quantity of chloroplatinic acid and evaporating to dryness on the steam bath. The residue was treated with successive portions of 93 per cent. alcohol till the greater part was dissolved, when the remainder was dried, a little more platinum solution added, and the procedure repeated. A little characteristic golden yellow residue was obtained.

(*a*) 0.995 g. chlorides gave 2.9 mg. K_2PtCl_6, equivalent to 0.08 per cent. K_2SO_4 in the original salt.

(*b*) 0.997 g. chlorides gave 3.3 mg. K_2PtCl_6, equivalent to 0.09 per cent. K_2SO_4.

The precipitated barium sulphate was also examined for potassium, but none was found in it. This quantity of another sulphate is, of course, too small to make any appreciable difference in the weight of our barium sulphate precipitates. The only other impurity noted in the sodium sulphate was a trace of iron.

Method of Precipitation.—The sulphate, dried as previously described, was, in some cases, weighed directly, but in general, to avoid exposing the anhydrous substance frequently to the air, a given quantity of salt was made up to a given weight of solution and weighed portions of this were taken for individual determinations.

pear that another and more important error is influenced by the same cause. In most of our work we have used one of two acid concentrations, *viz.*, 2 cc. of 2 per cent.[1] or 1 cc. 20 per cent. hydrochloric acid, the volume of the solution being 350 cc. The stronger acid has the advantage that the precipitates formed in its presence are somewhat denser and more convenient to handle, but the weaker acid is to be recommended, since the sum of the corrections in that case is smaller. The quantity of free acid *ordinarily* used in the sulphate determination is doubtless too great, and may cause large percentage errors on precipitates which weigh only a few hundred milligrams.[2]

The statement has been made by several chemists that alkaline chlorides greatly increase the solubility of barium sulphate.[3] Determinations of the solubility by the above method in solutions containing 10 grams sodium chloride in 350 cc. showed that the chloride was practically without influence. As these results were perfectly consistent with the rest of our work on sodium sulphate, nothing more was done on the question, but as regards the solvent effect of potassium and ammonium chlorides which is commonly held to be greater, we have definitely disproved that in another way (see Tables XX and XXV).

2. *The Occlusion*[4] *of Sodium Sulphate by Barium Sulphate.*—Table II gives a number of determinations of barium sulphate from a weighed quantity of sodium sulphate, and the corresponding deficits. It will

[1] For convenience, both will be stated in terms of 20 per cent. acid.

[2] Thus Folin (*J. Biochem.*, 1, 147 (1906)) prescribes as safe limits of acidity 1–4 cc conc hydrochloric acid in 150 cc. solution, *i. e.*, 4.5 cc. -18.5 cc. 20 per cent. acid in 350 cc.

[3] R. Fresenius and E. Hintz, *Z. anal. Chem.*, 35, 75 (1896); Lunge and Stierlin, *Z. angew. Chem.*, 18, 1929 (1905); Folin, *J. Biochem.*, 1, 142 and 144 (1906).

[4] By occlusion we mean, simply, retention by the precipitate without implying its nature.

be seen at once that the solubility correction (Table I) accounts for only a small part of the total loss.

In the sixth German edition of his "Quantitative Analysis" (Vol. I, p. 230, (1875)), Fresenius says that, when barium is precipitated by sulphuric acid in the presence of alkalies, small portions of alkali sulphates are carried down with the precipitate, but he gives no data. Hintz and Weber[1] found that, when barium sulphate, which had been precipitated from an ammonium sulphate solution, was heated in a glass tube, a sublimate containing sulphate was obtained. Lunge and Stierlin[2] give results of four determinations of sodium and potassium sulphates in crude barium sulphate, by digesting the latter with dilute hydrochloric acid. No evidence as to the completeness of the separation is offered.[3] We examined the weighed precipitate for impurities as follows:

The precipitate was dissolved in about 15 cc. pure conc. sulphuric acid in a platinum dish. The solution was cooled and poured in a thin stream into about 350 cc. water with vigorous stirring. The solution and precipitate were heated to facilitate filtering, after which the solution was evaporated over a free flame till fumes of sulphuric acid appeared, and then carried to dryness in a hood with good draft. The residue in the platinum basin was now dissolved in a little water and filtered through a 5.5 cm. filter into a small tared platinum dish. The contents were evaporated to dryness on the steam bath, then heated carefully to redness, cooled and weighed. The white soluble salt obtained could hardly be anything but sodium sulphate, nevertheless one of the residues was converted into barium sulphate and the point proved. 0 0234 gram residue gave 0 0386 gram $BaSO_4$; calc. for Na_2SO_4, 0 0385 gram. In order to find whether all the sodium sulphate is recovered from the precipitate by the above method, the precipitate obtained by pouring the sulphuric acid solution into water was dried, ignited, and again dissolved in sulphuric acid and reprecipitated by water. The results of four such experiments follow:

Na_2SO_4 (in mg.) from first extraction	10.1	11.8	24.8	26.2
Na_2SO_4 (in mg.) from second extraction	0.8	1.3	2.1	2.0

The second extraction recovers so nearly 10 per cent. of the amount obtained by the first extraction that in all subsequent data the amount *actually obtained* by one extraction will be given, but the correction will be made on a quantity 10 per cent. greater. This probably is as accurate as a direct determination would be.

Table III shows the amount of sodium sulphate found in precipitates formed under the conditions stated above, and also the corresponding corrections. Since all the sodium sulphate in the precipitate should, of course, have been converted into barium sulphate, the precipitate weighs too little. The numbers designated "correction" in the table are obtained by multiplying the weight of the occluded sodium sulphate, plus 10 per cent., by the factor $91.37/142.07 = (BaSO_4 - Na_2SO_4)/Na_2SO_4$.

---

[1] *Z. anal. Chem.*, 45, 39 (1906).

[2] *Z. angew. Chem.*, 18, 1921 (1905).

[3] We later discovered that water alone will extract from an *ignited* precipitate about 80 per cent. of the alkali salt.

TABLE III.—OCCLUSION OF SODIUM SULPHATE BY BARIUM SULPHATE.
Na_2SO_4 (in mg.) occluded by 2 grams precipitate[1] with the corrections.

0.2 cc. 20 per cent. HCl..	8.7	7.1	9.1	5.3	8.3	4.7	11.9	11.6

Corrections.............	8.1	5.9	8.0	8.4	7.2	5.0	5.4	6.5

This sodium sulphate is originally present as such in the barium sulphate. It is not present in the form of sodium chloride, as one might suspect. At least, this is true of the *ignited* precipitates. We have repeatedly tested our precipitates for chlorine by the quick and accurate method of Hulett and Duschak.[2] This consists in dissolving the precipitate in sulphuric acid, in a simple apparatus of glass swept by a current of air which carries the free hydrochloric acid into a solution of silver nitrate. We heated directly with a small flame, instead of a hot water bath, as Hulett and Duschak did, thereby dissolving the precipitate in a much shorter time, though now and then a determination is lost by the cracking of the tube. The silver chloride was determined gravimetrically instead of volumetrically, which was more convenient and sufficiently accurate for our purpose.

Precipitates prepared and washed as we have directed in the foregoing never gave more than 0.5 mg. of chlorine *after ignition*, and we have repeatedly reduced the quantity to 0.1 mg., even when the original solution contained 15 to 30 grams sodium, potassium, or ammonium chloride per liter. This is shown in Table IV. We will later show that the washed, but unignited, precipitates contain usually 1–2 mg. of chlorine, which is probably present as barium chloride; this is considerably increased when the precipitate is rapidly formed. The chlorine is practically all lost on ignition, if the precipitate has been slowly formed.

[2] *Loc. cit.*, p. 197.

The next step in the investigation was naturally to study the causes which condition the occlusion of sodium sulphate by the precipitate.

Influence of Various Factors on the Composition of the Precipitate.

(*1*) *The Effect of Concentration of the Sodium Sulphate.*—Table V gives a comparison of the quantities of sodium sulphate found in 2 grams barium sulphate precipitated from sodium sulphate solutions of several concentrations, the other conditions remaining the same. It will be seen that increasing the volume from 350 to 2000 cc. reduces the quantity slightly. The last two experiments are instructive. Equivalent solutions of barium chloride and sodium sulphate, each 100 cc. in volume and of such a concentration as to give about 2 grams of barium sulphate, were allowed to drop slowly and at the same rate (100 cc. in about 4 hours) into 8 liters of cold water, which was vigorously stirred during the whole process. The conditions in the two experiments differed only in the amount of acid in the solution. The quantity of sodium sulphate occluded, instead of being reduced by this high dilution, was a trifle increased thereby, though possibly this increase may be due to the fact that these precipitates were thrown down in the cold. It is evident from this that dilution alone is of little influence in reducing occlusion of sodium sulphate.

TABLE V.—EFFECT OF CONCENTRATION OF SODIUM SULPHATE.

Quantities of sodium sulphate occluded by 2 grams precipitate.

Volume in cc.	cc. 20 per cent. HCl	Mg.						
350	1	11.6	8.4	11.4	12.0	10.3	.	...
1000	5	6.0	8.9	. .		..	.	. .
2000	10	8.0	6.9	6.9	8.2	8.9	6.4	5.3
8000	5	10.9	[precipitated cold]					
8000	25	9.6	[precipitated cold]					

(*2*) *Effect of the Rate of Addition of the Reagent.*—The rate at which the solution is precipitated has some influence on occlusion, though it is not very great. Thus, if the reagent is allowed to flow as rapidly as possible from the burette (time = 9 seconds in the burette we used), the quantity of sodium sulphate taken up by the precipitate is reduced somewhat, though the results here are not so uniform as they are when the rate is slower (see p. 603).

(*3*) *The Effect of Pouring the Sulphate into the Barium Chloride.*—The few results obtained in this way indicate that no effect is to be attributed to this cause. In the three following experiments the barium chloride solution was diluted to 350 cc., acidified, and heated to boiling. Then the sulphate solution in 50 cc. volume was poured as slowly as possible into it with constant stirring. In three different experiments, the quantities of sodium sulphate occluded in 2 grams precipitate were 11.6 mg., 8.4 mg., and 12 mg.

(4) *The Effect of Acid Concentration.*—The concentration of the hydrochloric acid in the sulphate solution was found to reduce the occluded alkali sulphate very slowly, as may be seen from Table VI, but free acid increases the other errors more than it diminishes this one.

TABLE VI.—EFFECT OF ACID CONCENTRATION ON OCCLUSION.

Na_2SO_4 (in mg.) in 2 grams precipitate. V = 350 cc.

cc. 20 per cent. HCl.	0.2.	1.	5.	10	20.	100.
..	8.7	7.1	7.7	4.1	3.6	2.5
..	9.1	7.7	..	5.1	..	.
...	7.1	9.4	..	..	.	..

(5) *Influence of Time.*—There is a noticeable change in the composition of the precipitate if it is left to stand in the supernatant liquid. A precipitate which is filtered and washed immediately after precipitation always contains more sulphate than one which has been left to stand, and the difference is considerable when the initial quantity of occluded sodium sulphate is large.

TABLE VII.—EFFECT OF THE TIME OF STANDING ON OCCLUSION.

Mg. sodium sulphate in 2 grams precipitate.

Time. Hours.	Vol. cc.	NaCl. Gms	cc 20 per cent. HCl						
1/4	350	0	0 2	11.9	11.6	...	..		..
1/4	350	5	0.2	22.6	22.7		.		...
3	350	5	0 2	18.3	19.0	18.5	19.7	18.4	19.7
3	2000	0	1.0	6.9	6 9	8.2	8.9	.	
18	350	0	0.2	8.7	9.1		.		
18	350	5	0.2	17.3	17 1	17.5	17.2	17.9	....
18	2000	0	1.0	8.0	5 3	6.4	.	.	. .
45	350	0	0.2	5.3		.	..	..	...
45	350	5	0.2	14.0	14.2	.	...	...	....
70	350	5	0.2	12.6	11 9	...	....	..	....

(6) *Effect of Digesting the Precipitate.*—In order to test this point, a number of precipitations were made in the usual way from solutions of sodium sulphate containing 5 grams sodium chloride and 0 2 cc. 20 per cent. hydrochloric acid. Of these precipitates two were allowed to stand in contact with the original supernatant liquid for three hours on the steam bath; the precipitate was then filtered off, and the occluded sodium sulphate, determined in the usual way, was (1) 18.3 mg., and (2) 19.0 mg. In the other four cases, the supernatant liquid was poured off immediately after the precipitation and the precipitate was treated as follows, the time of contact with the liquid being in each case three hours on the steam bath.

	Amount of Na_2SO_4 in mg.
(3) Filtered and washed ppt. until free from Cl.; added 350 cc. hot water.	18.4
(4) Added 350 cc. hot water..............................	19.7
(5) Added 350 cc. hot water containing 1.2 grams Na_2SO_4....	18.5
(6) Added 350 cc. hot water containing 1.0 gram $BaCl_2$..............	19.7

From these results it is evident that the amount of sodium sulphate still occluded by the precipitate at the end of three hours on the steam bath, is independent of the composition and concentration of the supernatant liquid. The explanation of these results appears to be that the impurities in the precipitate react chemically with one another, forming barium sulphate and sodium chloride, and that it is the latter—not sodium sulphate—which diffuses out into the supernatant liquid (see paragraph 5). At any rate, it is evident that in an analysis nothing is gained by digesting the precipitate with a large excess of reagent.

(7) *Influence of Concentration of Sodium Chloride.*—It has been shown that a considerable variation in the concentration of a sodium sulphate solution exerts only a small influence on the content of the same in the barium sulphate precipitated from it. When the concentration of the sodium is increased by adding *sodium chloride* to the original solution, the occlusion of sodium sulphate is markedly increased. In Table VIII this influence is brought out. It appears that a concentration of sodium chloride of about 30 grams per liter causes an error of about 0.75 per cent. of the total sulphur from this source alone. The importance of this error is evident when it is remembered that alkali chlorides are commonly present in considerable quantity in solutions which have to be analyzed for sulphur. The effect of concentrations of chlorides greater than the above were not studied. Again, it should be stated that the presence of sodium chloride does not occasion the occlusion of the chloride as such. The ignited precipitates contain only a minute trace of chloride. Later we found that precipitates before ignition contained a small quantity, but the evidence goes to show that it is present as barium chloride, and that it is partly eliminated as hydrochloric acid during ignition.

TABLE VIII.—EFFECT OF SODIUM CHLORIDE ON THE OCCLUSION OF SODIUM SULPHATE.

The Volatilization of Sulphuric Acid when Precipitates Are Heated.

In many instances the losses due to solubility and the occlusion of sodium sulphate, together, make up nearly the whole deficit in sulphate determinations, but in others, *e. g.*, where the quantity of acid or of sodium chloride is considerable, the loss still unaccounted for may be equal to the sum of the above-named errors. As we could conceive of no other possibility, we tried experiments to find if the precipitates lost anything when they were heated.

To this end precipitates prepared and washed as usual were dried (in a toluene bath) at 105°. They were then carefully detached from the paper by tapping, and put into a tubulated platinum crucible (Gooch's) adapted to the determination of any volatile product.[1] The joint between cover and crucible was sealed with sodium tungstate, and the outlet tube was connected with a Liebig potash bulb which contained 10 cc. water and 1 cc. Merck's perhydrol free from sulphur. A current of pure dry air was drawn through the apparatus while the crucible was heated strongly by means of a Bunsen burner, the outlet tube from time to time being also heated with the free flame to drive out the volatile products. The contents of the bulb proved to contain sulphuric acid when tested in the usual way. A large number of subsequent experiments showed that barium sulphate precipitates thrown down from acidified sodium sulphate solutions, *always* lose sulphuric acid when they are ignited in this way. The tubulated crucible was used for all the earlier determinations given in this paper. For the greater losses caused by the chlorides of potassium and ammonium, it gave, for some reason, results entirely too low. A platinum combustion tube[2] and boat were therefore substituted. The tube must be heated with a blast, otherwise the barium sulphate in the boat does not reach a temperature comparable with that in an ordinary sulphur determination. In cases where the loss is large, two bulbs are required for complete absorption. Perhydrol must be used in the bulbs, otherwise there is a partial loss of sulphur dioxide which is formed by the dissociation of the sulphuric acid. Blanks were tried at various times but no trace of sulphuric acid was ever obtained from any of them. At first it was suspected that the volatilized sulphur came from a decomposition of the barium sulphate. This was disproved by the fact that the precipitates soon reach a constant weight, a point which is further supported by the work of Mostowitsch,[3] who found that barium sulphate does not appreciably dissociate under 1400°. The possibility of a reduction of the sulphate to sulphide, either by fibers of filter paper or by the hydrogen of the flame passing through the hot platinum, and a decomposition of the sulphide by moisture at the same time, was also considered. The flame surely had nothing to do with the case, because the results were the same when the crucible was heated by a resistance furnace to a temperature of about 1000°. Numerous tests on precipitates which had been heated in either way proved that they were not alkaline after ignition. These tests were very carefully conducted with hot boiled water and a drop of phenolphthalein. The solution never changed color; isolated grains sometimes turned pink, but a drop of 0.01 *N* acid was sufficient to dispel the color. This sets at rest any question of the decomposition of barium sulphate. Finally, it was shown that the quantity of sulphuric acid lost by volatilization varies greatly according to the conditions under which the precipitate was formed, but keeps pace with the deficits found on precipitates prepared under parallel conditions. Experiments showed that nearly all the loss occurs above 500°, but to heat the precipitates to this temperature would not remedy the difficulty; firstly, because water is retained by the precipitate at that temperature, and secondly, because the real difficulty is the failure to convert the sulphuric acid into barium sulphate during precipitation.

---

[1] See W. F. Hillebrand, *Bulls. U. S. Geol. Surv.*, Nos. 305 and 422, where the apparatus is described and applied to the determination of water in minerals.

[2] The authors wish to acknowledge their indebtedness to Mr. P. H. Walker, of the Bureau of Chemistry, for the loan of the combustion tube.

[3] *Metallurgie*, 6, 450 (1909).

Influence of Various Factors on the Loss by Volatilization.

In general, these factors are the same as those which condition occlusion; but the degree of their influence is different.

(*1*) *Effect of Acid Concentration.*—Table IX shows how this loss varies with the concentration of hydrochloric acid in the solution from which the barium sulphate is thrown down. The loss is given in terms of barium sulphate, since the sulphuric acid volatilized should have been converted into barium sulphate during precipitation. It will be noted that the loss increases with the strength of acid up to 5 cc. of 20 per cent. hydrochloric acid in 350 cc., and then falls again. As said before, nearly all our work has been done with 0.2 cc. and 1.0 cc. of 20 per cent. hydrochloric acid in a total volume of 350 cc. (lines 2 and 3). Here the loss seems nearly proportional to the acid concentration, which again is a reason for using the smaller quantity of acid. If the sulphate is poured into the barium chloride instead of *vice versa*, the volatilization losses are reduced. Two different precipitates, of about 2 grams each, formed in

[1] The figures marked [1] were derived by doubling the results obtained on 1 gram.

this way, in solutions containing 1 cc. 20 per cent. hydrochloric acid, lost sulphuric acid which yielded 0.3 mg. and 0.8 mg. barium sulphate, respectively. The quantities marked 1 in the table were derived by doubling the results obtained from 1 gram of precipitate, thus showing that the losses are proportional to the weight.

(2) *Effect of Sodium Chloride.*—Table X shows that when barium sulphate is precipitated from solutions containing sodium chloride, the acid remaining constant, the loss by volatilization is greatly increased. As chlorides are usually present where sulphates are to be determined, the importance of this fact will be instantly recognized.

(3) *Influence of Time.*—The data on this point show higher losses when precipitates are filtered and washed immediately after precipitation, and a gradual reduction of the losses when the precipitates are allowed to stand in contact with the supernatant liquid. A few data on this point are given in Table X. Where accuracy in the determination of sulphur is required, it is therefore evident that there is a real gain in allowing the precipitate to stand. We have shown that the errors, both from occlusion of sodium sulphate and from volatilization, are in this direction and the same must be true of "solubility," if there is any difference at all.

TABLE X.—EFFECT OF NaCl ON VOLATILIZATION LOSS.

H_2SO_4 (in mg. $BaSO_4$) lost by 2 grams precipitate.

(4) *Effect of Rate of Addition of the Reagent.*—We have stated previously that the rate at which the reagent is added to the solution makes little difference in the quantity of alkali sulphate retained by the precipitate. The loss by volatility, however, is markedly lowered by increasing the rate (Table XI).

The Composition of Rapidly Formed Precipitates.

The direct and natural inference from the results in this table is that rapid precipitation reduces the amount of "free" acid in the precipitate. A closer study proved this to be true. Rapid precipitation has also another effect, *viz.*, to increase the quantity of chlorine in the precipitate.

---

[1] Averages from Table IX.

Indeed, all *unignited* barium sulphate precipitates contain chlorine, however carefully they are washed. Four solutions of identical composition, *viz.*, 1.21 grams Na_2SO_4 + 5 grams NaCl + 0.2 cc. 20 per cent. hydrochloric acid in 350 cc., were precipitated in pairs, two slowly and two rapidly. The time for each of the first pair was 3–6 minutes, for the second pair 9 seconds. After the usual washing, these precipitates were dried at 105°. The chlorine was determined by Hulett and Duschak's method. 6.3 mg. and 7.2 mg., respectively, of silver chloride were obtained from the first pair, the 17.8 mg. and 20.9 mg. from the second pair. We have previously seen that the total sodium is slightly diminished by a rapid precipitation, which could not be the case were the chlorine taken up in the form of sodium chloride. Now, since barium sulphate, which is precipitated from *sulphuric acid*, also contains chlorine which Hulett and Duschak have shown to be likewise increased by rapid precipitation, and which in their case must be in the form of barium chloride, we conclude that the chlorine in all the precipitates is in the same form.

Since both "free" sulphuric acid and barium chloride exist together in the same precipitate, it is not surprising to find that during ignition some hydrochloric acid is always volatilized, formed, of course, by the chemical reaction of the two substances. We at first supposed that by this means the rapidly formed precipitates, containing as they do more chloride, reduced the volatilization of sulphuric acid. But experiment showed that the amount of hydrochloric acid thus formed is about the same, whether the precipitate had been formed slowly or rapidly; consequently the washed precipitate must contain *less* "free" sulphuric acid in the latter case. A slowly formed precipitate loses, in this way, practically all its chlorine, but a rapidly formed precipitate still contains a considerable amount. Two such precipitates formed in solutions containing 5 grams NaCl + 0.2 cc. 20 per cent. hydrochloric acid in 350 cc. retained 10.3 mg. and 10.8 mg. chlorine (in terms of silver chloride).[2] In spite of this fact, we may still lose several milligrams of sulphuric acid (in terms of barium sulphate) on heating. After ignition one may extract from such a precipitate both sodium chloride and sodium sulphate, though not the total quantity of the sodium (Table XII).

---

[1] The values given for slow precipitation are average values from Tables IX and X.

[2] Our precipitates are thus, at least partially, analogous in composition to Hulett and Duschak's, though apparently the amount of sulphuric acid their precipitates absorb, if any, is always less.

TABLE XII.—WATER EXTRACT (IN MG.) FROM IGNITED PRECIPITATES.

We have treated the subject of rapid precipitation so much in detail because it has been advocated as the essential condition of an analytical method for the determination of sulphur by Hintz and Weber.[3] From the preceding it will now be understood that the losses by volatilization of sulphuric acid and occlusion of sodium sulphate are in the first place reduced by reason of a more complete conversion of the original sulphate into barium sulphate, and in the second place, partially compensated by an absorption of barium chloride by the precipitate. Our own results, obtained by rapid precipitation, which are given in Table XIII, prove it

[1] Presumably only Na_2SO_4 remained in the precipitate; chlorine was not tested for.

[2] Had an extraction with sulphuric acid, instead of water, been made, all would have been changed to sulphate.

[3] *Z. anal. Chem.*, 45, 31 (1906).

[4] After ignition the chlorine is doubtless present in the precipitate as sodium chloride; still it makes no difference whether it is regarded as combined with sodium or barium. The sodium is always more than equivalent to the chlorine and we may regard (1) all the chlorine as $BaCl_2$ and all the sodium as sulphate, or (2) all the chlo-

far superior to the ordinary slow precipitation. It should be stated that the conditions we followed were not exactly those recommended by Hintz and Weber. They used 1 cc. conc. hydrochloric acid in 450 cc., and, having previously diluted the reagent to 100 cc. and heated to boiling, poured it in all at once. We adopted the variations in the hope of greater uniformity. The results obtained are, in fact, similar to theirs, both in uniformity and accuracy. They are not so reliable as the corrected results when the precipitation is done slowly, but they are often surprisingly good.

Total Sulphuric Acid Occluded by Barium Sulphate Precipitates.

It is now evident that the total quantity of free sulphuric acid originally present in all barium sulphate precipitates is greater than that lost by volatilization; a part of it is held back by the barium chloride which the precipitates also retain, and an equivalent of hydrochloric acid is volatilized in its place. Although no part of the analytical problem, we regarded it as a matter of some interest to determine the total quantity of sulphuric acid occluded under various conditions. Accordingly, the volatile products were collected as usual and both the hydrochloric and sulphuric acids were determined in each. Table XIV shows the quantities of hydrochloric acid (in terms of silver chloride) which are lost by precipitates formed under stated conditions. Table XV gives, in parallel columns, the quantities of hydrochloric acid volatilized, in terms of sulphuric acid, and the quantities of sulphuric acid which are lost as such.

TABLE XIV.—EFFECT OF RATE OF PRECIPITATION ON CHLORINE[1] VOLATILIZED IN THE IGNITION OF PRECIPITATES

				1 7	1 9	3 6									

A comparison of the figures for slow and rapid precipitation shows that the hydrochloric acid volatilized is not much influenced by the rate of precipitation, though it is usually a little greater when the precipitation is rapid The results on page 600 show, however, that the *total* chloride present in the precipitate is much increased by the rate at which it is thrown down It follows that rapidly formed precipitates must occlude less free sulphuric acid, and thus a rapid rate of formation reduces the volatility loss

The Correction of Sulphate Determinations.—The following tables (XVI-XVIII) contain a series of determinations of sulphur in sodium sulphate under stated conditions, giving the proper corrections for "solubility," occlusion, and volatility. From the horizontal lines designated "deficit" the original percentage loss may be seen to vary

Table XIX gives corrected determinations of sulphur in the presence of various quantities of sodium chloride—a very common case in practice. The errors range from 0.8–1.8 per cent. before correction and are reduced by correction to from 0.03–0.14 per cent. with a mean error of only 0.08 per cent.

The determinations given in Tables XVI, XVII and XVIII are uniform enough to make satisfactory corrections by the use of the constants which are the means of the different determinations. Thus, in Table XVIII, the constants are, for 2 grams precipitate, volatility, Vy., = 2.2 mg.; occlusion, Oc. = 5.1. For solubility in this case individual cor-

rections are required because Experiments 1 and 2 were filtered after 18 hours, the rest in a short time. In one or two instances, also, a little fine precipitate was washed over the top of the paper and was recovered in the filtrate, thus increasing the usual correction. In Table XVI, the average corrections are Vy. = 0.3 mg., Oc. = 5.7 mg., Sy. = 1.0 mg., total = 7.0 mg. In Table XVII, the corrections are: Vy. = 0.6 mg., Sy. = 1.0, Oc. = 7.5, total = 9.1. Here the average cannot be applied quite so well as the individual corrections. In Table XIX, which includes cases where sodium chloride is originally present, Vy. and Oc. are much larger and both are quite sensitive to conditions. It is wise in such cases to apply individual corrections, making a duplicate precipitation under identical conditions, on which the volatility is determined.

B. The Precipitation of Potassium Sulphate by Barium Chloride.

The same sources of error occur in precipitating barium sulphate from potassium as from sodium sulphate.

Losses Due to "Solubility."—The loss from solubility is of the same order of magnitude and is increased only very slightly by the addition of potassium chloride to the sulphate solution, in spite of the statements to the contrary, already quoted (see p. 592). It is not surprising that many who have noted large errors in the determination of sulphur where alkali chlorides are present should have suspected that these were due to solubility. Of course, if this view is correct, the loss will depend, not on the quantity of the precipitate, but on other conditions, chiefly the volume and composition of the solution. Our results show, on the contrary, that the errors depend on the quantity of the precipitate, *i. e.*, they are percentage errors.

A weighed quantity of one of our precipitates, which had been heated to redness, was put into a beaker, to which was added 10 g. potassium chloride, 350 cc. water, and 0.2 cc. 20 per cent. hydrochloric acid. This was heated to boiling and kept on the steam bath, with occasional stirring, for several hours. Then it was left to stand over night. Next morning it was filtered on a small filter, washed free of chlorine and weighed.

	Gram		Gram
$BaSO_4$ taken	0.0683	Found in precipitate	0.0668
$BaSO_4$ found	0.0694	" " filtrate	0.0026
$BaSO_4$ loss	0.0011		0.0694

Objection might be taken to the use of a *heated precipitate* here, on the ground that there might be an irreversible change in barium sulphate on heating, leaving finally another phase of different solubility. A microscopic examination made by Dr. F. E. Wright, of this laboratory, showed that the index of refraction of the substance was little affected by heating. It remained about 1.63, the value for natural barite, and in no other respect did the substance appear to be changed, except that the crystallization became somewhat coarser. Still, to leave no doubt in the matter, further experiments were tried on the unheated substance.

A weighed quantity of pure dry potassium sulphate was dissolved in 350 cc. water, with given quantities of potassium chloride and hydrochloric acid. The solutions were precipitated boiling hot by 0.5 cc. more than the calculated quantity of barium chloride, kept hot a few hours and allowed to stand over night, after which the procedure was similar to that in the experiment just described.

	..		.		.	2.8	1.2	..	.
	..	...	.	..	1.3[2]	1.4[2]	..	1.2[2]	1.4[2]
Mean...... .. .	0.9	0.9	2.5	0.9	2.1	2.4	1.2	1.2	1.4

[1] This value is the mean of those given in Table I, line 1.

[2] In these determinations the total quantity of $BaSO_4$ was less than 0.1 gram; in all the others, it amounted to 2.0 grams.

Thus the barium sulphate recovered from the filtrate is not only of the same order of magnitude as it is where no alkaline chloride is present, but the total loss is greatly reduced when the mass of the precipitate is reduced. The evidence is very clear that potassium chloride has no influence on the solubility of barium sulphate within the limits of error of this method Table XXI compares the solubility losses occasioned by the chlorides of sodium, potassium, and ammonium (which will be treated in detail in the next section), with the losses found when no chlorides are originally present.

Occlusion of Potassium Sulphate—Barium sulphate occludes sodium and potassium sulphates in about equal quantity when the conditions are similar. The correction for potassium sulphate, 59/174 = $(BaSO_4—K_2SO_4)/K_2SO_4$, is, however, evidently less The quantity of potassium sulphate obtained from a precipitate by a single extraction with sulphuric acid (see p. 593) is about 80 per cent of the total quantity

		Mg	Mg	Mg.
1st extraction K_2SO_4	=	16 1	19 1	3 4
2d extraction K_2SO_4	=	3 3	4 8	0 7

It will be within the limits of experimental error, since the total quantities are so small, if we make a single extraction and add to the quantity obtained 25 per cent. more. The corrections in Tables XXIII and XXIV are made in this way.

Loss by Volatilization.– Precipitates from potassium sulphate lose notably more on ignition than precipitates from sodium sulphate. Even with very weak acid (0 2 cc. 20 per cent in 350 cc.) and no potassium chloride in the original solution, the losses are 0 3 per cent. from this source alone if the precipitation is slow; with 10 grams potassium chloride and the same concentration of acid, the losses reach 0 7 per cent., and with 10 grams potassium chloride and 1 cc. 20 per cent hydrochloric acid, 1 5 per cent. Others have noticed greater losses when potassium chloride was present, but have ascribed them to increased solubility. The data are tabulated in Table XXII.

Chlorine.—The chlorine is negligible in ignited precipitates from potassium sulphate, if the precipitation is slow.

Correction of Sulphur Determinations.—The corrected results in Table XXIII, on the sulphur in potassium sulphate, leaves little to be desired. The losses vary from —0.07 per cent. to +0 07 per cent. If potassium chloride is present in quantity, the important conditions to be followed are a small quantity of free acid and close attention to rate of precipitation. In Tables XXIV, Nos. 3, 5, 6, and 7, the rate was carefully regulated by attaching to the burette a capillary tip, both in the determination itself and in the duplicate precipitations for the determination of the volatility loss. Although the errors are large, the final losses vary, from —0.07 to +0 06 per cent. Nos. 1, 2, and 4 were done at an earlier stage of the work; they were precipitated more rapidly and without measuring the rate. The corrections which were made on precipitates slowly formed are therefore not applicable to them; the sum of the corrections is greater than the deficits, as our study of the composition of barium sulphate precipitates shows should be the case

C. Precipitation of Ammonium Sulphate by Barium Chloride.

So far as the composition of a precipitate from ammonium sulphate is concerned, it does not differ essentially from precipitates previously considered, *i e.*, it contains ammonium sulphate, "free" sulphuric acid, and chlorine in quantities which increase with the rate of precipitation. This case differs from all others, however, in one respect—that the ammonium sulphate in it is almost entirely volatile at a red heat, therefore the loss from occlusion is much greater than it is in other cases.

The ammonium sulphate used in all the experiments described was entirely volatile at a red heat. It was dried to a constant weight at 130°.[1]

Losses Due to Solubility.—The influence of ammonium chloride on the solubility of barium sulphate has been treated exactly like the influence of potassium chloride, and it is shown in Table XXV that when small quantities of sulphur are determined in solutions containing ammonium chloride the total losses are almost negligible; hence the great losses when the quantities of sulphur are large could not be due to solubility

TABLE XXV —DIRECT DETERMINATION OF THE SOLVENT INFLUENCE OF AMMONIUM CHLORIDE ON BARIUM SULPHATE

Precipitation of $(NH_4)_2SO_4 + NH_4Cl$ + 0 2 cc 20 per cent HCl, V = 350 cc

NH_4Cl Grams	$(NH_4)_2SO_4$ Gram	$BaSO_4$ calc Gram	$BaSO_4$ found in ppt Gram	$BaSO_4$ found in filtrate Gram	Loss

10	0 0281	0 0495	0 0471	0 0024	0

Ammonium Sulphate Occluded by Barium Sulphate—This was determined on 2 gram precipitates as follows:

The precipitate dried at 105° was dissolved in about 15 cc. concentrated sulphuric acid with gentle warming, cooled and poured into about 250 cc. cold water and filtered. The filtrate was then distilled with a slight excess of pure soda, and the distillate collected in excess (10 cc. 20 per cent.) of dilute hydrochloric acid. The latter was evaporated almost to dryness on the steam bath, then further with addition of platinum chloride. The ammonium chloroplatinate was separated with alcohol and dried at 130° in the usual way. The ammonium was calculated by the use of the empirical factor 0 081.[2] Not improbably one extraction with sulphuric acid may fail to remove the total quantity of ammonium sulphate, but, judging from experience with sodium and potassium sulphates, the amount left in the precipitate cannot be large, and since the exact quantity is not needed for correction purposes, this point was not settled.

An inspection of the data in Table XXVI shows that the losses from occlusion ($BaSO_4$ equiv.) are equal to about 1 2 per cent. of the total sulphur under the above conditions. The quantity of ammonium sulphate occluded by the precipitate varies little with the rate of precipita-

---

tion; it is slightly less when the rate is rapid, just as it is with sodium and potassium salts. After the precipitates have been ignited, as the table shows, they contain only a trace of ammonium sulphate. It may be noted in passing that we have here a simple method for preparing pure barium sulphate.[1]

Loss by Volatilization.—We have seen in the preceding paragraph that all but a trace of the occluded ammonium sulphate is lost by heating, and, since this should have been converted into barium sulphate, the loss is comparatively large. The *total* loss by volatilization is still greater, because these precipitates, in complete analogy with others which we have considered, contain also "free" sulphuric acid. Table XXVII gives the losses due to volatilization. The column headed "free sulphuric acid" is obtained by difference. The determination of the total volatility gave a good deal of trouble. Very low results were obtained with the tubulated crucible. This may have been due to the retention of some of the sulphate by the sodium tungstate used to seal the joint. The platinum combustion tube and boat gave, when sufficient heat was applied, nearly correct results. As previously stated, two bulbs should be used for complete absorption.

TABLE XXVII.—LOSSES BY VOLATILIZATION (IN MG.) FROM 2 GRAMS PRECIPITATE

		11.1	24.4	5.5	29.9	25.9	9.6	35.5

Correction of Sulphate Determinations.—The following determinations in Table XXVIII will serve to show the magnitude of the losses, when sulphur is determined in ammonium sulphate, with or without ammonium chloride. It hardly need be said that these errors, reaching 2 per cent. at the maximum, would be very considerably increased in the presence

---

[1] These two precipitates were ignited before testing for ammonium.

of more free acid. These data also make it evident why ammonium salts should be avoided, if possible, in solutions where sulphur is to be determined. Nevertheless, although the errors are large, it will be noticed in the table that the sum of the corrections very nearly make up the deficits found in actual determinations. It is therefore possible to get very good results in the presence of ammonium salts by applying the proper corrections.

D. Precipitation of Magnesium Sulphate by Barium Chloride.

Hulett and Duschak[1] found that magnesium sulphate gave, with barium platinocyanide, precipitates which agreed in weight with the calculated quantity. Their explanation was that the impurities in precipitates formed from sulphuric acid and barium chloride were due to the formation of complex salts by the union of intermediate ions; *e. g.*

$$2BaCl' + SO_4'' = \begin{matrix} Ba-Cl \\ Ba-Cl \end{matrix}\Big\rangle SO_4 \text{ and } 2HSO_4' + Ba'' = \begin{matrix} HSO_4 \\ HSO_4 \end{matrix}\Big\rangle Ba.$$

To us it seemed not improbable that the purity of the precipitates from magnesium sulphate might be due to the fact that barium sulphate has not the power to occlude magnesium sulphate while it can occlude the sulphates of the alkalies. If this view is correct, any salt of barium would do as well as the platinocyanide. The sequel shows that barium chloride, at least, gives similar results.

A standard solution of magnesium sulphate was prepared in the following manner. A solution of sulphuric acid of about the right strength was titrated against pure anhydrous sodium carbonate (heated to 300°). This was then neutralized by pure magnesium oxide and diluted to a definite weight. Details follow:

58.470 grams H_2SO_4 soln. required 1.0495 grams Na_2CO_3

55.946 grams H_2SO_4 soln. required 1.0042 grams Na_2CO_3

The titration was made at boiling temperature using phenolphthalein as indicator. Making corrections for buoyancy of the air,

---

[1] *Loc. cit.*

1 gram sol. = 0.016589 gram H_2SO_4 or 0.039488 $BaSO_4$.
1 gram sol. = 0.016591 gram H_2SO_4 or 0.039500 $BaSO_4$.

500.05 grams of this solution were now transferred to a platinum basin and evaporated with magnesium oxide (which had been especially freed from lime, sulphuric acid and water) until litmus paper showed that the solution was neutral. The undissolved excess of magnesium oxide was filtered off and thoroughly washed. It retained after washing 0.0173 gram SO_3. $BaSO_4$ found = 0.0503. The solution with washings was cooled and again diluted in a tared flask to a given weight, *viz.* 500.17 grams. After making corrections for buoyancy and subtracting the sulphur found with the undissolved magnesia, 1 gram solution = 0.039384 gram $BaSO_4$.

The results in Table XXIX are all obtained by the slow precipitation of weighed quantities of this standard solution under the same conditions as are found described on page 590. These data reveal the fact that very little magnesium sulphate is found in the precipitate, and show that the errors are much smaller than they are with the alkali sulphates. The volatility loss was a mere trace, immeasurable in three instances; in one case 0.3 mg. barium sulphate was found. In accord with this the chlorine is a little higher, though always less than 1 mg. As seen from the table, the original errors range from 0.01 to 0.21 per cent. in seven instances, while one result is 0.27 per cent. low.

TABLE XXIX.—CORRECTED RESULTS FOR $MgSO_4$.

	0.2 cc. 20 per cent HCl.		1 cc 20 per cent HCl.				2 cc. 20 per cent. HCl.		Average.

Loss..........	—1.1	—3.2	4.7	1.3	—0.6	—1.9	2.9	0.2	2.0

The results have been corrected for solubility, which was determined with two concentrations of acid, for magnesium sulphate and for chlorine. As shown on pages 602-3, it makes no difference whether we assume that magnesium chloride + magnesium sulphate are present, or that all the magnesium is in the form of sulphate and the chlorine in the form of barium chloride. The corrected results are only a trifle better than the uncorrected.

The Effect of Nitrates on the Precipitation of Barium Sulphate.

According to statements found in the literature,[1] nitrates must removed from solutions in which sulphur is to be determined, otherwise the results are too high Our work confirms these assertions We have tried only the nitrate of sodium, but the same is probably true of potassium nitrate. Table XXX shows that when as little as 1 g of nitrate is contained in 350 cc. solution, the results are nearly 0 5 per cent. too high Five grams nitrate caused an error of 0 8 per cent and 10 grams nitrate had practically the same effect The cause of the error is not far to seek The table shows that the precipitates contain an unusual amount of sodium. One of them when boiled with water, gave up free alkali very slowly Evidently, the precipitate occludes the nitrate, which forms caustic soda on ignition On account of the hygroscopic nature of the impurity, the readiness with which it attacks platinum, and, moreover, the readiness with which it is avoided, it was not thought worth while to study this subject any further It has been suggested that the low results obtained in the determination of sulphur might be compensated by the addition of the correct amount of nitrate to the solution before it is precipitated. A fair degree of approximation might perhaps be reached in this way.

Nature of the Precipitate.

We have seen that barium sulphate precipitates even when thrown down from solutions of rather simple composition are, nevertheless, themselves pretty complex. The form in which the impurities are held in the precipitate is a question worthy of interest. The facts indicate that not all of them sustain the same relation to it. The barium chloride, for example, is present in very small quantity (about 0 15 per cent.) in slowly formed precipitates, reaching several times that quantity in those which are rapidly formed. Now, as rate of formation is a condition which especially governs the fineness of the precipitate, and the finest precipitates contain the greatest amount of this impurity, it is natural to conclude that we have here a case of adsorption. Hulett and Duschak made similar observations in the precipitation of barium chloride by sulphuric acid. Rapidly formed, fine-grained precipitates contained the most barium chloride; one in particular, which was formed very slowly indeed, contained only 0.03 per cent.

of chlorine (about 0.08 per cent. barium chloride). If the substance were held in a purely mechanical way, one would expect all the impurities to be increased, diminished or removed by the same conditions. This, as we have seen, is not the case. It is equally difficult to see how the alkali sulphate in the precipitate can be retained mechanically. Not only are the different impurities differently affected by the same conditions, but the absorption is a markedly selective phenomenon. No alkali chloride seems to be taken up, nor are all the sulphates. The sulphates of sodium, potassium, ammonium, ferric iron, and probably aluminium,[1] are absorbed, while magnesium sulphate (see p. 613) is scarcely absorbed at all. The selective nature of the absorption indicates a solid solution The fact that barium sulphate has an affinity for other sulphates is in accord with this What we may call the secondary conditions seem to change comparatively little the quantity of the sulphate which is taken up. After a precipitate has been ignited the greater part of the soluble sulphate may be extracted by water (Table XII).

It is not unusual to find that the solubility of one salt in another decreases markedly with rise in temperature, but one would expect the system to return to its former state on cooling. The rapidity of the cooling, however, might prevent this. On the other hand, the mechanical conception would explain this fact as well. The ignition might be supposed to disrupt compact grains of the precipitate, thus exposing the soluble impurities to the action of the solvent.

The "free" sulphuric acid in the precipitate may be supposed to have been dissolved in the form of acid sulphate of the alkali metal. The quantity decreases much with rapid precipitation, which may mean that the fine-grained material is changed more readily by the barium chloride, on standing in the supernatant liquid. We know that the sodium sulphate changes somewhat also, but to a less extent.

At present there seems to be little prospect of adding to our knowledge of such fine-grained substances by microscopic investigation, so that we are not even certain of the homogeneity of the precipitates, and we are free to confess, in conclusion, that the facts we have accumulated are insufficient to decide the question of their true nature.

Summary.

1. The errors in the determination of sulphur in soluble sulphates have been investigated for those cases which most frequently occur in experimental work. Solutions of sodium, potassium, ammonium and magnesium sulphates have been studied, both in a state of purity and in the presence of varying quantities of hydrochloric acid and alkali chlorides. In a few systems the influence of sodium nitrate has also been studied.

---

[1] Schneider, *Z. physik. Chem.*, 10, 425 (1895); Creighton, *Z. anorg. Chem*, 63, 53 (1909).

2. The most important sources of error are three in number, one arising from the solubility of the precipitate and the others from its composition. Two minor sources may also be mentioned.

a. The error from solubility depends chiefly on the quantity of free acid present. Contrary to the common belief, we find that the chlorides of sodium, potassium, and ammonium exercise a hardly appreciable influence on it. Under easily regulated conditions (0.2 cc. 20 per cent. HCl in 350 cc. original solution) it amounts to 1–2 mg. only. It is self-evident that this error (almost negligible for precipitates of 1 g. or more) becomes increasingly important, the smaller the precipitate.

b. All barium sulphate precipitates carry down with them quantities of the alkaline sulphates, varying with many conditions. In the case of pure acidulated sulphates, this quantity is not far from 0 5 per cent. It is especially affected by alkali chlorides, and may be more than doubled in this way. The correction depends of course on the atomic weight of the alkali metal. About 0 75 per cent. is the maximum quantity of ammonium sulphate absorbed by precipitates under conditions which have been investigated by us; the correction for it is, however, comparatively large (1.25 per cent.), because ammonium sulphate is entirely volatilized when the precipitate is ignited. Magnesium sulphate is scarcely absorbed at all by barium sulphate. The peculiar selective adsorption which barium sulphate exhibits, suggests the formation of solid solutions. The evidence on the subject is, however, too meager for a proof.

c. Barium sulphate, when precipitated from alkali sulphates, always occludes a certain amount of "free" sulphuric acid, which is probably taken up as acid sulphate of the alkali metal. It arises, of course, from the free acid added to the original solution and increases with it up to a certain point. Alkali chlorides decidedly increase the amount of it, and in the presence of much of the latter, it becomes the chief source of error. Aside from one or two qualitative observations, this loss seems to have been thus far entirely overlooked. It is greater for potassium than for sodium sulphate solutions. In one case a solution of the former containing 10 grams KCl and 5 cc. 20 per cent. HCl in 350 cc. lost 1.7 per cent. in this way.

d. All barium sulphate precipitates contain barium chloride. If the precipitation is made slowly (3–6 min. for 2 grams $BaSO_4$), the amount of this is only about 0.15 per cent. in the unignited precipitate, and since all but a trace of it is eliminated as hydrochloric acid during ignition, it is not a source of error. When a precipitate is very rapidly formed the amount of the barium chloride is multiplied several times and the chlorine is no longer entirely eliminated on ignition. The more rapid the precipitation, the finer the precipitate, and since the barium chloride retained increases with the fineness, we regard it as probably held by adsorption. The other impurities are diminished by rapid precipitation.

e. Sodium nitrate, and probably other nitrates also, are occluded by barium sulphate, giving results which are therefore too high.

3. An exact determination of sulphur, so far as we know, can only be done by correcting for the above-named errors. Nitrates are to be avoided, also chlorides and ammonium salts as far as possible. Corrections for occlusion and solubility can be made directly, but for volatility, unless one has a specially constructed platinum apparatus, a duplicate precipitation must be made under identical conditions.

We recommend the following conditions: Acidulate the solution (V = 350 cc.) with 2 cc. 2 per cent. hydrochloric acid and heat to boiling. Precipitate slowly (about 4 min. for 2 grams precipitate) with constant stirring. The rate may be regulated by a burette with a capillary tip attached. Let the precipitate stand 18 hours before filtering; the losses from occlusion and volatility are both considerably higher when the filtration is done immediately. Filter on paper and wash till 25 cc. of the washings show a barely perceptible opalescence with silver nitrate. Burn very slowly and carefully and heat over the burner to a constant weight. To this result should be applied the corrections for the errors just discussed. If the solution contains only alkali sulphate and known quantities of alkali chloride and hydrochloric acid, and if the directions above are carefully followed, the correction constants determined by us may be applied. A more accurate result might perhaps be reached by the application of corrections experimentally determined for the case in hand. Detailed methods for these are given in the body of the paper. In unknown mixtures of alkali chlorides the corrections must, of course, be actually determined. To correct for the occlusion in such cases it would only be necessary to take the weight of the mixed alkali sulphates extracted from the precipitate, to convert them into barium sulphate and weigh; the difference between the weights of the barium sulphate and the mixture is the correction. A carefully corrected determination of sulphur for the cases given should be accurate to 0.1 or 0.2 per cent. of the total sulphur. A very good uncorrected determination may be obtained by precipitating *rapidly*, but it is due to partial compensation of variable errors, and is not in any case so reliable as one which is made by slow precipitation and corrected as described.

The authors wish to express their thanks to Dr. W. F. Hillebrand for reading the manuscript of this paper, and for suggesting a number of emendations.

ON THE FORMATION OF DOUBLE SALTS.

By H. W. Foote.

Received February 22, 1910.

The object of this investigation was to determine the influence of various organic solvents on the formation of certain double salts which yield hydrates when crystallized from water. The facts regarding simple salts are much better known than those regarding double salts. Thus, Menschutkin,[1] among many others, has shown that an organic solvent may replace the water of crystallization in many cases, so that a salt crystallizing at a given temperature with a certain number of molecules of water will crystallize from an organic solvent with the same number—sometimes with a smaller number—of molecules of that solvent. Again, the water of crystallization of a simple salt can ordinarily be removed by suitable means, leaving the stable anhydrous salt, and the water of crystallization is in general not necessary in order that the salt itself should be formed. Whether the water, or more generally the solvent, of crystallization is necessary in order that a double salt shall form and whether the solvent affects the type of salt formed, has been but little investigated. Almost the only work on the formation of double salts from non-aqueous solutions has been done recently by Cambi,[2] but it is somewhat difficult to draw conclusions from his work which apply to the present problem, as it is not certain in the cases investigated by him that all the double salts capable of forming at a given temperature from any one solvent are known.

For the present investigation, the double salts of mercuric chloride with sodium and potassium chlorides were chosen. The double salts which these chlorides form from water at 25° have already been determined.[3] These salts, all containing water of crystallization, have the following composition:

$NaCl.HgCl_2.2H_2O$
$2KCl.HgCl_2.H_2O$
$KCl.HgCl_2.H_2O$
$KCl.2HgCl_2.2H_2O$

Mercuric chloride is much more soluble in some organic solvents than it is in water, and the alkali chlorides have an appreciable solubility in these solvents when mercuric chloride is present. Absolute alcohol was used as solvent for sodium and mercuric chlorides and both absolute alcohol and acetone were used when potassium chloride was present. The alcohol was purified by treating with sodium and distilling. The acetone was dried over anhydrous copper sulphate and distilled.

The same solubility method has been used for determining double salts that was previously used in determining the double mercuric chlorides formed from water. By this method, all salts forming from a solvent at a given temperature can be definitely determined. Varying proportions of the salts and solvent were mixed together in small bottles with ground glass stoppers. The salts were weighed and the volume of liquid measured to serve as guides in making other mixtures. The salts very often formed in lumps when first brought into contact with the liquid, due to the formation of double salts. When the lumps could not be broken by shaking they were crushed with a glass rod. The stopper and neck of the bottles were dipped in melted paraffin to make them perfectly water-tight and were then shaken in a thermostat, usually for 48 hours. A sample of the solution was then drawn through a filter of glass wool into a weighed specimen tube and analyzed. The residue was removed and dried on filter paper. Both solvents are very volatile and there was some evaporation as the salts were dried between filter papers. This tended to contaminate the residues with salts from the solution, so that the composition of the residues could not be determined with the same accuracy as the solutions.

Both solutions and residues were analyzed by precipitating mercury as sulphide from hydrochloric acid solution, filtering on a Gooch crucible, and drying at 110–120°. The filtrate was evaporated to dryness and the alkali determined as chloride. Alcohol or acetone crystallizing with the double salts was determined by difference except when otherwise stated. In the mixtures containing sodium and mercuric chlorides, the residues were not analyzed but their composition was calculated. This could be done with sufficient accuracy, since the composition of the solution and of the original mixture were known.

The following results were obtained:

TABLE I.—SOLUBILITY OF SODIUM AND MERCURIC CHLORIDES IN ABSOLUTE ALCOHOL AT 25°.

In the tables just given, a series of two or more results showing constant solubility and varying residue indicates a mixture of two salts, while variable solubility and constant composition of the residue show the presence of a pure double salt. Referring to Table I, it will be seen that the solubility of the mixtures remains practically constant, showing that the same solid phases are present in every case. The residues vary in composition from nearly pure mercuric chloride to sodium chloride containing only twelve per cent. of mercuric chloride, so that no double salt can be present and the residues consist of varying proportions of the single salts. This conclusion will perhaps be clearer if the results are considered in another way. If a double salt were present, the residue in No. 1 would consist of a mixture of the double salt and mercuric chloride, and No. 3 would consist of the double salt and sodium chloride. As different solids are present in the two cases, the solubilities would be different. The fact that this is not the case shows that the same solids are present. These can only be the single salts, as the composition of the residue varies between such extreme limits.

Sodium and mercuric chlorides therefore do not form any double salt at 25° from absolute alcohol. From water, the salt $NaCl.HgCl_2.2H_2O$ forms. The conclusion appears justified that the water of crystallization is essential to the formation of the double salt, and if the water were removed from the double salt it is to be expected that the residue at 25° would consist of an uncombined mixture of the single salts.

The results in Table II show that one double salt of potassium and mercuric chlorides forms from absolute alcohol at 25°. This salt forms under wide conditions. It was present in pure condition in Nos. 3 and 4 of the table, where the solubility varies. Nos. 1 and 2 consist of a mixture of the double salt and mercuric chloride and Nos. 5–7 of a mixture of the double salts and potassium chloride. The double salt appears to be of an unusual type. A sample was prepared by dissolving mercuric and potassium chlorides in hot alcohol in such proportions that only three or four grams crystallized from about 300 grams of alcohol containing but a small percentage of mercuric chloride. The hot solution was placed in the thermostat at 25° and deposited a mass of silky needles of the double salt. They appeared pure under the microscope. The solution, after standing in contact with the double salt, contained 6.8 per cent. of mercuric chloride, also showing that the pure double salt was present. The salt was removed from the mother liquor, dried very rapidly between filter paper, and analyzed. Alcohol was determined directly by Penfield's method for water. The results, with those previously obtained (Nos. 3 and 4, Table II), are given in Table IV, also the calculated composition of two assumed double salts.

TABLE IV.—RESULTS OF THE ANALYSES OF THE DOUBLE SALT FORMING FROM ALCOHOL.

No.	KCl.	$HgCl_2$	Alcohol.
3	17.63	78.00	4.37 (Diff.)
4	18.27	77.29	4.44 (Diff.)
(Crystallization)	17.07	77.82	4.76 = 99.65
Calculated for $5KCl.6HgCl_2.2C_2H_6O$	17.84	77.76	4.40
Calculated for $3KCl.3HgCl_2.1C_2H_6O$	20.67	75.08	4.25

The three analyses agree among themselves as closely as could be expected, considering that they were all formed under different conditions. The results agree with the formula $5KCl.6HgCl_2.2C_2H_6O$, which is a new type of salt so far as known. The results are so different from the calculated composition of the simpler 3 : 3 : 1 salt that it appears necessary to accept the more complicated formula.

The results, using acetone as solvent, are in Table III. A pure double salt was present in Nos. 3–5 and another in Nos. 8–11. The first corresponds fairly well with the 1 : 5 : 1, the calculated composition of which is given in the table. The results showing the composition of the second salt (Nos. 8–11) vary considerably, as would be expected from the wide variation in the composition of the solutions from which the salt formed. Acetone is much more volatile than alcohol and evaporates so fast that the residues were considerably contaminated with salts from the solution. No. 11 should be the purest sample, as it formed from a solution containing the smallest amount of dissolved salts. It agrees fairly well with the calculated composition of the 5 : 6 : 2 salt, which forms also from alcohol. The salt can be recrystallized. Mercuric chloride and potassium chloride were therefore dissolved in hot acetone in the proportion in which they are present in the 5 : 6 : 2 salt and the solution was allowed to crystallize at 25°. The analytical results were:

	Found.	Calculated for $5KCl\ 6HgCl_2.2C_3H_6O$.
$HgCl_2$	77.52	76.87
KCl	17.46	17.64
C_3H_6O	5.02 (Diff.)	5.47

Acetone is lost rapidly by both salts in the air, so this constituent varies considerably from the calculated values in most of the analyses.

The salts with potassium chloride obtained from the three solvents are summarized in the following table:

From water.	From alcohol.	From acetone.
....	....	$KCl.5HgCl_2.C_3H_6O$
$KCl.2HgCl_2.2H_2O$	....	......
....	$5KCl.6HgCl_2.2C_3H_6O$	$5KCl.6HgCl_2.2C_3H_6O$
$KCl.HgCl_2.H_2O$	....	....
$2KCl.HgCl_2.H_2O$	....	....

It will be noticed that none of the types of salts formed from water are formed from the other solvents, and further, that the 1 : 5 : 1 salt from acetone is not formed either from water or from alcohol. The 1 : 5 salt without water has, however, been prepared with rubidium and with caesium.

From the results obtained in this investigation the conclusion may be drawn that when a double salt is formed containing the solvent, the latter is an essential constituent of the salt and is as important in determining the type of double salt formed, as are the individual salts. The substitution of one solvent for another may even prevent a double salt from forming.

SHEFFIELD CHEMICAL LABORATORY,
NEW HAVEN, CONN.

ADDITIONAL NOTES ON THE ALKALI AND ALKALI EARTH AMALGAMS.

BY G. McP. SMITH AND H. C. BENNETT.

Received March 8, 1910.

The problem as to the nature of the solid amalgams was first systematically investigated by Kerp,[1] who carried out exact solubility determinations with certain members of the class. In every case the solid as well as the saturated solution in equilibrium with it was analyzed.

---

[1] *Z. anorg. Chem.*, 17, 284 (1898).

In a second paper,[1] by Kerp and Böttger, the solubility determinations were continued, and the results were interpreted according to the phase rule. The various phenomena which are possible are discussed at length by Kerp and Böttger. By determining for various temperatures the composition of each of the phases in equilibrium, Kerp and Böttger were in a position to judge whether the solid phase, owing to its constant composition at different temperatures, was to be classed as a chemical individual, and, if so, between what temperatures it was capable of existence.

An undoubted disadvantage of Kerp and Böttger's method lies in the fact that it is extremely difficult to completely separate the crystalline amalgams from the adhering mother liquor, which renders the analytical results for the solid phases very uncertain.[2] For example, the work of Maey,[3] which is free from this error, has rendered the existence of the compound $NaHg_6$, described by Kerp and Böttger, very uncertain.

In our work on the electrolytic preparation of the alkali and alkali earth amalgams,[4] in which large quantities of the solid amalgams were at our disposal, the crystals left behind on filtration showed in several instances a higher alkali content than was obtained by Kerp and Böttger. We therefore repeated their work, at the ordinary temperature, with the addition that the mother liquor left behind on filtration was removed as far as was possible, without undue risk of oxidation, by means of a high-speed electric centrifugal machine. We have included caesium amalgam, which Kerp and Böttger did not prepare, and have also in certain cases repeated their solubility determinations.

Unless otherwise stated, the solid amalgams, obtained by filtration through chamois skin on the filter pump, were introduced into narrow glass tubes (internal diameter = 8 mm.), in which they were melted; while in this condition, the ends of the tubes were vigorously tapped upon the desk, in order to jar to the surface the air bubbles and any hydroxide which might be present. The tubes were then sealed off just above the surface of the melt. They were later cut into 3-centimeter sections, and the amalgams were removed in the form of compact, crystalline sticks, which were centrifuged at high speed for 5–10 minutes in open Gooch crucibles, without filters. Samples weighing 1–8 grams, from which the outer, slightly tarnished surfaces had been removed with a knife, were then at once analyzed. The samples were covered with water (to which a few drops of methyl orange were added), 0.1 *N* hydrochloric acid was run in just to neutral reaction, an excess was then added, and, after the decomposition of the amalgam, this was titrated back with 0.1 *N* sodium hydroxide. The water had acquired its alkalinity, which was generally equivalent to about 1 cc. of 0.1 *N* acid, from the oxidation products present; its action on the amalgam itself was negligible. The alkali content of an amalgam was therefore calculated from the volume of acid that was required to actually decompose the amalgam.

Caesium amalgam, in the form of crystalline sticks, was rapidly oxidized in the centrifuge. Large crystals, obtained by allowing the liquid amalgam, saturated at the ordinary temperature, to stand for several hours in cracked ice, were, however, centrifuged at high speed for 5 minutes without apparent oxidation. Two samples, weighing 7–8 grams, gave, on analysis, 5.05 and 5.07 per cent. of caesium. This was the highest caesium content we obtained. In the cases of sodium and lithium amalgams the crystalline sticks remained compact throughout the treatment, and the results are considered reliable. On disintegrating the solid sticks of the centrifuged sodium amalgam, fine, needle-like crystals of a splendent metallic luster were obtained. To the eye they showed no sign of oxidation, and, unlike those of caesium, rubidium and potassium amalgams, they were clean-cut and free from any indication of mother-liquor. The results for the crystalline amalgams are given as a whole in Table I:

TABLE I.

[1] Kerp and Böttger had very little crystalline lithium amalgam to work with, which necessarily increased the difficulty of separating the mother liquor by filtration on the filter pump. Their low result is evidently due to the presence of mother liquor.

From the last three columns in the table it is seen that, in spite of the disadvantages of the method, the results tend to indicate the existence of compounds of the formulas $CsHg_{12}$, $RbHg_{12}$, KHg_{12}, $NaHg_5$, $LiHg_3$, $BaHg_{12}$ and $SrHg_{12}$. Nevertheless, the numerical results are misleading, and the only indications which are to be regarded as reliable are those for the sodium and lithium compounds. In the other cases the results prove only that, in the general formula $MeHg_n$, the maximum value of n is 12. It is curious that, in the case of lithium amalgam, Kerp and Böttger, by filtration, obtained values in agreement with the formula $LiHg_5$, while we, by filtration, arrived at the formula $LiHg_4$, and by means of the centrifuge at the formula $LiHg_3$. From his work Maey[1] deduced the existence of $LiHg_5$, of $LiHg_3$ and of other compounds richer in lithium. His results, however, do not so unmistakably indicate the existence of $LiHg_5$, as they do that of $LiHg_3$.

Kerp,[1] in his original paper, did not observe the compound $NaHg_6$, and Kerp and Böttger account for this on the assumption that the compound was decomposed during filtration by the pressure that was then exerted upon its surface in order to completely remove the mother liquor. In their common paper[1] they take exception to the work of Maey, which failed to indicate the existence of a compound richer in mercury than $NaHg_5$. Maey[1] determined the specific volumes of amalgams of varying composition, and from the specific-volume curves he deduced the existence of certain definite compounds. Among others, he determined the specific volume of an amalgam containing 1.90 per cent. of sodium ($NaHg_6$ requires 1 88 per cent.) and obtained the value 0 08168. The next amalgam contained 2.63 per cent. of sodium, and for it he obtained the specific volume 0.08545. We have determined the specific volume of an intermediate amalgam, which contained 2.12 per cent. of sodium ($NaHg_5$ requires 2.25 per cent.) and have obtained the value 0.08277. It is evident that the compound $NaHg_5$ could not have resulted from a specifically heavier one through the agency of pressure alone. Neither is it at all likely that the solid sticks of amalgam were heated much above the ordinary temperature in the centrifuge. Our results harmonize with those of Maey in denying the existence, at the ordinary temperature, of a compound of the formula $NaHg_6$.

Table II contains the weight of amalgamated metal that is present in 100 grams of the saturated liquid amalgam. It should be borne in mind however, that these metals are not present in the solution in the free state; they are present in the form of compounds of the general formula $MeHg_n$, dissolved in an excess of mercury.[2] In the table our own determinations are indicated by asterisks. The other values are those of Kerp and Böttger, which are given for the sake of comparison.

In conclusion, it is desired to offer an explanation of the well-known fact that, although mercury itself will not adhere to such metals as iron and platinum, even very dilute alkali and alkali-earth amalgams do readily adhere to them. Upon dipping a platinum wire covered with adhering amalgam into dilute hydrochloric acid, the alkali metal is extracted and the resulting mercury does not continue to adhere to the platinum. It has been shown[2] that, in the decomposition of these amalgams with hydrochloric acid, a point is reached at which there is a sudden increase in the surface tension of the amalgams, accompanied by the sudden evolution of a cloud of minute hydrogen bubbles, and by a sudden decrease in the solution pressure of the amalgams. It would appear, therefore, that the adhesion of the amalgams to platinum and to iron is due rather to the inferior cohesion of the amalgams than to any chemical reaction.

SOME NEW DOUBLE ARSENATES.[3]

BY LOUIS J. CURTMAN.

Received March 11, 1910.

The work on double phosphates[4] suggested the preparation of corresponding arsenates, especially as reference to the literature showed that such compounds had not been prepared. The method which was found to yield these salts was similar to that employed in the preparation of the double phosphates, except as regards the acidity of the solution, which in this case was somewhat greater.

---

[1] We were unable to prepare an amalgam containing more than 0.09 per cent. of calcium. It was filtered at 23°, and was entirely liquid.

[2] THIS JOURNAL, 31, 31 (1909).

[3] Presented in abstract before the Boston Meeting of the American Chemical Society, December, 1909.

[4] THIS JOURNAL, 29, 714 and 1194 (1907).

Preparation.—A solution consisting of 100 cc. of 10 per cent. ferric chloride, 50 cc. of hydrochloric acid (sp. gr. 1.2) and 50 cc. of water was heated to 70°. To this was added gradually and with constant stirring a hot solution of diammonium arsenate containing 105 grams in 175 cc. of water. The addition of the arsenate was followed by the formation of a temporary precipitate which, dissolving on stirring, had the effect of weakening the color of the iron solution; the latter became perfectly colorless when nearly the entire quantity of the arsenate had been added. On adding the last few cc., a slight white gelatinous precipitate formed, which, on heating and stirring, increased in amount and at the same time changed to a finely granular form resembling chalk. The mixture was continuously heated with stirring on an asbestos pad until the temperature rose to 100°, after which it was digested on a boiling water bath for one hour and then allowed to stand overnight. The next day the clear, colorless, supernatant liquid was siphoned off and the residual, perfectly white, compact mass washed twice by decantation with an alcoholic solution (1 part 95 per cent. alcohol to 2 parts of water) containing 0.1 per cent. of ammonium chloride, and then finally with alcohol (1–1) till the washings were free of chlorides.[1] The filtrate was acid to litmus and gave strong tests for ammonium and arsenate, showing that an excess of the precipitant had been used; it did not contain any iron.

The precipitate was first allowed to partially dry in the air, then pulverized, and finally dried to constant weight in a water oven. The yield was 12 grams.

Analysis.—The ammonium was determined by direct distillation with caustic soda into a standard acid solution. The arsenic and the iron were determined in another portion by the following procedure: About one gram of the material was dissolved in 10–15 cc. of conc. hydrochloric acid; when solution was complete, 50–75 cc. of a strong solution of sulphurous acid were added, the whole transferred to a small pressure bottle, and the latter stoppered and heated in a boiling water bath for one hour. After cooling, the contents of the pressure bottle were transferred to an Erlenmeyer flask and without heating, the arsenic was precipitated with a rapid stream of hydrogen sulphide. The filtrate and washings were at once treated with filtered compressed air to drive out the hydrogen sulphide, evaporated to a small bulk, filtered, and the iron determined gravimetrically as Fe_2O_3, or volumetrically with a standard potassium permanganate solution by the Zimmerman-Rheinhart method. The well washed precipitate of As_2S_3 and S was dissolved in concentrated hydrochloric acid with the addition of potassium chlorate, boiled to expel the excess of chlorine, filtered from the undissolved sulphur into a standard volumetric flask and diluted to the mark. Aliquot portions were then pipetted out, rendered alkaline with ammonia, and the arsenic precipitated in the usual way with magnesia mixture and ultimately weighed in a Gooch crucible as $Mg_2As_2O_7$.

---

[1] The final washings, though free of chlorides, gave a test for AsO_4.

	Found.		Theory for $(NH_4)H_2AsO_4$ $FeAsO_4$.
NH_4	4.71	4.66	5.08
Fe	15.45	15.63	15.81
As	42.12	42.06	42.37

Properties of $NH_4H_2AsO_4.FeAsO_4$.—The double arsenate of ferric iron and ammonium is a white powder possessing a faint greenish-yellow tint. It readily dissolves in cold conc. hydrochloric acid with the formation of a yellow solution; it is also soluble in hot nitric and in hot dilute sulphuric acids. Arsenic acid containing 75 per cent. arsenic pentoxide readily dissolves it on heating, yielding a colorless solution from which ammonia, even when added in excess, failed to reprecipitate the arsenate, but instead gave a reddish brown solution, the color of which varied with the amount of double salt originally dissolved. It is insoluble in 50 per cent. acetic acid, also in a strong solution of ammonium chloride. Caustic alkalies completely hydrolyze the compound, the final product being ferric hydroxide; hot water has a similar effect, only to a smaller degree. Hot strong ammonia dissolves the double salt with the formation of a deep red solution. On gentle ignition the double arsenate decomposes, giving off ammonia and water.

Action of Water.—As the chief characteristic of the corresponding double phosphates is their readiness to undergo hydrolysis when washed excessively with water,[1] it was thought worth while to determine whether or not this was the case with the double arsenate and thus explain the difficulty of obtaining a product of a high degree of purity. Accordingly, about two grams of the analyzed salt were treated in a bottle of two liters capacity with 1500 cc. of water at the laboratory temperature, repeatedly shaken, and finally allowed to stand overnight. The next day nearly all the material had settled to the bottom; a very small portion, however; remained in suspension in the colloidal form, which could not be removed by the usual process of filtration. As standing for three days did not cause the colloidal material to settle, recourse was finally had to a porcelain filter operated by strong suction; this proved effective. The residual solid material after the water treatment was noticeably yellow, thus indicating hydrolysis. It was returned to the bottle and treated again with 1500 cc. of water, shaken, allowed to stand overnight, and filtered. The residue which was dried over sulphuric acid possessed a light brown color. Analysis of the clear concentrated aqueous extract showed the presence of AsO_4 and ammonium, but contained no iron. Analysis of dried brown residue after the two treatments with water gave: NH_4, 2.27; Fe, 19.24; As, 31 11.

[1] THIS JOURNAL, 29, 717. "Ueber die Phosphate des Kupfers," Doctor's Dissertation, Halle, 1890.

Comparison of these figures with those obtained for the normal salt shows that the action of water on the salt consists in dissolving out arsenic acid and ammonium, accompanied by a change in color of the compound due to the formation of ferric hydroxide. The action is one of *hydrolysis*, precisely similar to that observed with the corresponding phosphates.

Action of Ammonia.—The solubility of the double salt in ammonia suggested the possibility of the formation of basic double arsenate of ferric iron and ammonium similar to that prepared from the corresponding double phosphate. A small quantity of freshly prepared double ammonium ferric arsenate was treated in an Erlenmeyer flask with concentrated ammonia and the mixture heated on a boiling water bath; the white precipitate first became yellow, then brown, and finally, on further heating, dissolved completely to a beautiful reddish brown solution. On adding 95 per cent. alcohol to this solution, a curdy, reddish brown precipitate settled to the bottom and was at once filtered from the overlying cloudy liquid. A portion of the reddish brown material, nearly completely dried in the air, was treated with water; it entirely dissolved to a yellow solution. The ammoniacal filtrate containing an excess of alcohol possessed a very pale yellow color and gave a strong test for arsenic acid with silver nitrate after neutralization of the ammonia with acetic acid. Another portion was evaporated to dryness, taken up with hydrochloric acid and tested for iron. The slight tests obtained indicated that the filtrate contained only traces of iron. Qualitative analysis of the dried precipitate obtained with alcohol showed the presence of iron, arsenic, and ammonium, but the amount was too small for a quantitative analysis. Its qualitative analysis taken, together with its physical properties, namely, color and solubility in water, strongly suggest the corresponding phosphate which forms under the same condition. This will be further investigated.

When dipotassium arsenate was used in place of the ammonium compound, under the same conditions which were found favorable for the formation of the double arsenate of iron and ammonium, a white precipitate was obtained. The result of a qualitative analysis of this substance indicates the existence of the corresponding double alkali arsenate. This compound, together with the double arsenates of aluminium and chromium, are under investigation at the present time.

Summary.

If to a hot ferric chloride solution, strongly acid with hydrochloric acid, diammonium arsenate solution be added to incipient precipitation, and the mixture heated, there forms a white, finely divided precipitate, which analysis showed to be a double arsenate of ammonium and iron of the formula $NH_4H_2AsO_4.FeAsO_4$. Like the corresponding phosphate prepared by the author, the double arsenate readily hydrolyzes when washed with water. It readily dissolves in mineral acids, but is practically insoluble in 50 per cent. acetic acid. Ammonia dissolved it on heating to a deep reddish brown solution, from which 95 per cent. alcohol precipitates a basic double ammonium ferric arsenate. When potassium arsenate was used under the same conditions, a precipitate was obtained which, from the results of a qualitative analysis, appears to be the corresponding double alkali arsenate.

NEW YORK CITY, February, 1910.

A STUDY OF THE PHENOLSULPHONIC ACID METHOD FOR THE DETERMINATION OF NITRATES IN WATER.

[SECOND PAPER.]

THE COMPOSITION OF THE YELLOW COMPOUND.

BY E. M CHAMOT AND D. S. PRATT

Received February 22, 1910

In our first paper[1] we discussed the composition of the various sulphonic acid reagents which have been suggested for use in this method[2] and showed that the standard phenolsulphonic acid generally used in the United States (Method Am. Pub. Health Association)[3] made by heating a mixture of 15 grams of phenol and 128 cc. of concentrated sulphuric acid for six hours in a flask immersed in boiling water, consists of phenoldisulphonic acid 1-2-4, with always small but appreciable quantities of phenolmonosulphonic acid (para) and a large excess of sulphuric acid. It was also stated that the yellow color obtained by treating a nitrate-containing water residue with this reagent, diluting and making alkaline, was not due, as had long been taken for granted, to salts of picric acid,[2],[3] nor could it be due to salts of mononitro phenols, as believed by Hazen and Clark,[4] nor to salts of dinitro phenols as Montanari supposed.[5]

It had already been shown by Andrews[6] that the mononitro and dinitro phenols are removed from acid solutions by shaking with benzene and that they may be removed from the solvent by shaking with water containing a small amount of alkali, yielding a yellow liquid. Andrews further showed that the nitrophenolmonosulphonic acids are insoluble in benzene and may thus be separated and differentiated from the nitro phenols. Making use of this method, Andrews concluded that mononitro and dinitro phenols and picric acid must be absent from the reaction product of phenolsulphonic acid on nitrates, and therefore assumed that the yellow color must be due to nitrophenolsulphonic acid salts; but as he apparently believed that the reagent consists of monopara acid,[1] one gathers from his paper that he believed the yellow compound to be a salt of the nitromonopara acid. This assumption as to the composition of the reagent and reaction product did not appear to be at all conclusive to the authors, who believed it very necessary to definitely determine the character and structure of the yellow compound by actual isolation and analysis, thus obtaining conclusive proof as to its nature.

[6] Andrews, THIS JOURNAL, 26, 388 (1904).

As stated in our first paper, it was found early in the investigation that when the cold reagent is poured upon cold residues (the usual method of procedure) no trace ot nitro phenols nor of picric acid could be detected in the reaction products when dealing with such amounts of nitrate as are usually met with in water analysis, 0 to 30 parts per million of nitrogen as nitrate. When, however, the amount approaches 50 parts per million, traces, but only traces of picric acid, appear and may be detected by microchemical analysis.

When either the reagent or the water residue is hot, or when the residue is heated after adding the reagent to it, different results are met with and under these conditions even 5 parts of nitrogen as nitrate may then give slight traces of picric acid, the amount increasing according to the heat treatment, but never reaching more than appreciable traces. The monoparasulphonic acid present is also nitrated by this heat treatment. The presence of these exceedingly small amounts of picric acid was proved by extracting with benzene a large number of water residues after treatment with phenolsulphonic acid, evaporating the solvent and subjecting the extracted material to microchemical tests. Picric acid could not, however, be detected unless a large number of water residues were extracted and hence this compound cannot legitimately be regarded as a product of the reaction as the method is carried out in practice.

In order to obtain the compound yielding the yellow color in alkaline solution, it was decided to isolate it from actual natural water residues containing nitrogen as nitrate. This source of material was adopted in order that there could be no question as to the reactions in the standard method, the authors believing that the pouring of the reagent on pure nitrate residues and the subsequent isolation therefrom of a yellow-colored salt might possibly be regarded as no proof of the products of the reactions obtained in practice.

---

[1] Since the preparation of this article, Lombard (*Bull. soc. chim.*, 6, 1092 (1909)) advances the theory based upon the work of Obermiller on phenolsulphonic acids, that the reagent consists chiefly of orthophenolsulphonic acid and paraphenolsulphonic acid and that the yellow compound consists of about 2 parts of alkali salts of orthonitro phenol and 3 parts of orthonitrophenolsulphonic acid. No details are [illegible] ver, to substantiate this conjecture, which is erroneous

Several thousand residues were obtained by evaporating to dryness, on a water bath, 100 cc. portions of a natural water containing about 10 parts per million of nitrogen as nitrates. These residues were then separately treated in the cold with 2 cc. each of the standard phenolsulphonic acid and the resulting products united. From this acid liquid no color-giving material could be extracted by benzene.

Experiments on a small scale demonstrated that it was possible to separate the yellow-colored salt from the other products present in the alkaline solution by fractional crystallization, and that the potassium salts were best suited for this procedure. Potassium was chosen as the base for several reasons. The reagent always contains a large excess of sulphuric acid and it is evident that the major portion of the products formed must be inorganic sulphates. It is therefore advantageous to have this of a low solubility and as easily crystallizable as possible, hence, potassium is more to be desired than either sodium or ammonium, any one of these three being used in the method. Moreover, potassium is better adapted to quantitative determination.

For the above reasons the acid liquid resulting from the combined residues was carefully neutralized with just sufficient potassium hydroxide solution to develop the maximum color, care being taken to avoid, as far as possible, a marked rise in temperature. The resulting solution was alkaline to litmus This yellow alkaline liquid was then subjected to fractional crystallization in the usual manner, by evaporation, pouring off mother-liquors and combining similar fractions. In another portion of the alkaline liquid fractional precipitation by means of alcohol was resorted to. In both cases potassium sulphate first separated, always, however, stained yellow. The yellow compound, being far more soluble, accumulated in the end fractions. It was soon evident that the compound under investigation was much more soluble in hot than in cold water. After the isolation and purification of the yellow salt, solubility determinations showed that 100 parts of water dissolve 28.8 parts at 40°, 100 parts of water dissolve 19.4 parts at 20° C. The solubility of potassium sulphate, on the contrary, is but slightly increased by a rise of temperature.[1] The fractionations were therefore carried on in warm solutions, making use for this purpose of a large incubator regulated for 40° in our bacteriological laboratory. No attempt was made to ascertain the most suitable temperature for fractioning, since 40° proved remarkably efficient and satisfactory, and this incubator temperature was available.

---

[1] Hazen [illegible] J. prakt. Chem., 29, 471.
Montanari, [illegible] water at 20° C. dissolve 11.11 parts K_2SO_4
Andrews, THIS [illegible] ater at 40° C. dissolve 14.76 parts K_2SO_4

Inasmuch as the reagent consists of phenoldisulphonic acid 1–2–4, together with a small amount of phenolparasulphonic acid, the possible products of the reaction are the normal and acid salts of the two nitrosulphonic acids, the unnitrated sulphonates, mononitro phenols, dinitro phenols, picric acid and dinitro phenolmonosulphonates. Of these compounds the unnitrated sulphonates are colorless, but the nitro compounds are all more or less yellow in alkaline solution.

Both Andrews, by his solubility method, and the authors, by microchemical analysis, have shown that mononitro phenols, dinitro phenols and picric acid are not products of the reaction. The authors have further shown[1] that under the usual method of procedure no nitro group is introduced into the parasulphonic acid. This leaves as the possible compounds formed, the alkali salts of nitrophenoldisulphonic acid and dinitrophenolmonosulphonic acid, the latter resulting from the replacement of one sulphonic acid group by a nitro group—such a reaction, in the cold and with such small amounts of nitric acids as are met with in water analysis, is, however, very improbable, theoretically. Moreover, no evidence of such a compound could be obtained by the authors in any of the material studied. By elimination there remains only the alkali salt of nitrophenoldisulphonic acid.

Nevertheless, as the fractionation proceeded, there separated what appeared to be two nitro compounds. Eventually this was found to be erroneous, one of these being a salt of phenoldisulphonic acid which in crystallizing always occludes relatively large amounts of the nitrosulphonate, thus acquiring shades of yellow, from which it can be completely freed only with great difficulty. Instead, however, of being the tripotassium salt as we assumed at first, because of the presence of a slight excess of potassium hydroxide, it proved, upon isolation and analysis, to be the dipotassium salt of this acid, $C_6H_3OH(SO_3K)_2.H_2O$. This salt is colorless when pure, crystallizing in highly refractive orthorhombic prisms, exhibiting exceptionally strong double refraction (Fig. 1). It cannot therefore be confused in microchemical examinations with the salt of the nitro acid.

The other yellow salt separating was fractioned to free it from potassium sulphate, until its solution failed to yield a turbidity with barium chloride. It was then recrystallized from water at room temperature.

---

[1] Chamot and Pratt, *Loc. cit.*

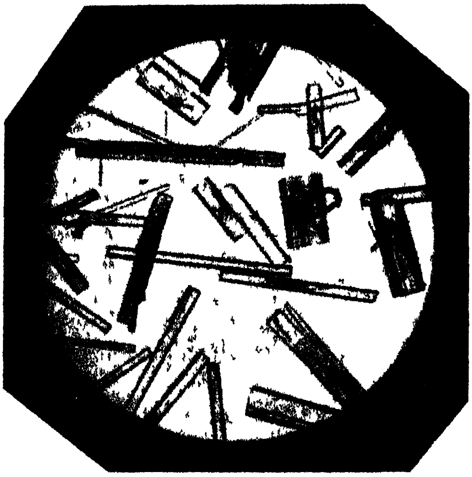

Fig 1 —Dipotassium phenoldisulphonate × 15

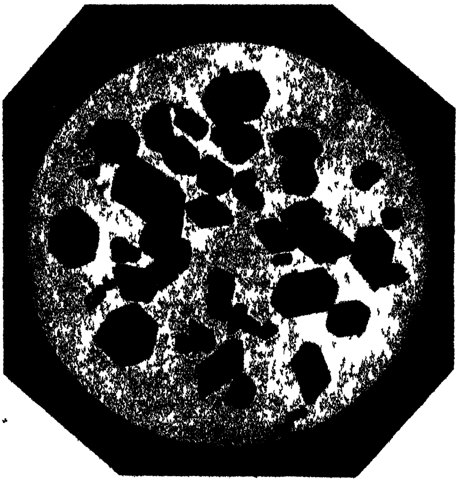

Fig 2 —Tripotassium nitrophenoldisulphonate × 15.

There was thus obtained between one and two grams of a beautifully crystalline, very brilliant, highly refractive orange-yellow salt.

Dry air passed over these crystals caused a loss of water of crystallization, as did heating to 100°. In attempting to dry to constant weight in air it was found that a gradual increase of weight took place, probably due to oxidation. To avoid this, a small electric resistance furnace was designed in which the heating could be done in an atmosphere of carbon dioxide under reduced pressure. This apparatus consisted of a short piece of Jena glass combustion tube wound with nickel wire and surrounded with asbestos-magnesia pipe covering. The temperature could be easily and accurately regulated by a resistance lamp-board and the material contained in platinum boats was readily accessible. The tube was partially exhausted by means of a Chapman filter pump and pure dry carbon dioxide was passed through to remove the moisture liberated. A temperature of 200° was found to be most convenient for removing the water of crystallization. Above 240° the compound turns brown and decomposes without melting. A determination of the melting point of the compound is therefore impossible.

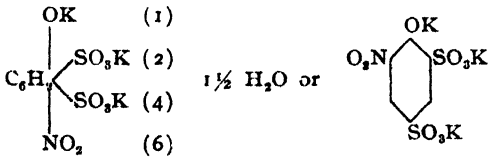
The air-dried, orange-yellow salt gave, upon heating as above described, a loss of weight corresponding to one and one-half molecules of water o crystallization.

Found: 6.16; 5.97; 6.45; 6.47; 6.09; average 6.22 per cent.
Theory for $C_6H_2OK.(SO_3K)_2.NO_2.1\frac{1}{2}H_2O$, 6.13 per cent.

The analysis of the anhydrous salt gave the following results:

	Per cent found			Theory for $C_6H_2OK\,(SO_3K)_2\,NO_2$.
K....	28.46	28.35	28.43	28.37
N....	3.43	3.45	...	3.37
SO_4	46.25	46.21	...	46.47

The salt therefore has the following formula:



$$C_6H_2\begin{cases}OK & (1)\\ SO_3K & (2)\\ SO_3K & (4)\\ NO_2 & (6)\end{cases}\; 1\frac{1}{2}\,H_2O \text{ or}$$

Potassium was determined as the chloroplatinate in the usual manner on the salt direct.

Nitrogen was determined by the Kjeldahl method after first reducing by boiling with zinc dust in a slightly acidulated solution.

For the determination of the sulphonic acid radical the material was first oxidized by several treatments with fuming nitric acid (sp. gr. 1.52) and subsequent precipitation with barium chloride,

This tripotassium nitrophenoldisulphonate crystallizes from aqueous solutions in beautiful orange-yellow, triclinic, many-sided prisms of high refractive index (Fig. 2).

Through the kindness of Professor A. C. Gill, of the Department of Mineralogy and Petrography, the following crystallographic note is given:

"The yellow salt occurs in stout prisms or tabular triclinic crystals. Most of the crystals were too small to measure, but one of the tabular ones, about 0 5 mm. in length, gave fairly good reflections on the goniometer. The plane angle of the large face was a little less than 70°. Each of the edges of the plate is formed by a pair of long, narrow faces. The angles from the top plate to the bottom over one pair are 70° 40′, 64° 25′, and 44° 55′, while over the other pair the angles are 52° 49′, 64° 47′, and 62° 24′. The prismatic habitus as shown in the photograph is much more common than the tubular habitus of the crystal measured.

"The crystals show pleochroism from orange- to sulphur-yellow, are strongly double refracting, and have marked dispersion both of the optic axes and axes of elasticity."

The anhydrous salt is quite a little darker orange in color than the hydrated, and when hot is a cherry-red, retaining its orange color upon cooling. In dilute solutions it is clear yellow but tends towards red as the concentration is increased. With ferric chloride solution it gives a violet-red. Acids added to its solution do not decolorize it, but simply weaken the tint, accounting for the yellow color always obtained in acid solution when a residue high in nitrates is treated with standard sulphonic acid.

A small amount of the dipotassium phenolsulphonate present in the fractions usually greatly modifies the crystal form of the tripotassium nitrophenoldisulphonate, and there may then appear, on rapid crystallization, blade-like crystals pointed at each end or sheaves or clusters of these crystals. It is these modified crystals which confused us for some time, as stated above.

The last fractions of a series always contain as an impurity the very soluble potassium salt of the monoparasulphonic acid, a small amount of this acid being always present in the standard reagent. This salt crystallizes in exceedingly slender and delicate hair-like tufts.

To determine whether the same product is always obtained when the amount of nitrogen as nitrate ranges between the usual limits present in water a special series of water residues was examined. These differed by increments of about two parts of nitrogen per million between the limits of 2 and 30. Each residue was treated with 2 cc. of the standard reagent, diluted and made alkaline with potassium hydroxide. In every case, by microchemical analysis, the yellow color was found to be due to tripotassium nitrophenoldisulphonate. A residue containing 60 parts nitrogen per million gave similar results.

In a third paper the authors will discuss the phenolsulphonic acid method as applied in practice with special reference to sources of error.

Summary.

The yellow color of alkaline solutions of nitrate containing water residues treated with standard phenolsulphonic acid reagent is due to the tripotassium salt of nitrophenoldisulphonic acid, this salt having been isolated and its properties studied.

No other compound giving a yellow color with alkalies could be isolated or detected in appreciable amount, in treated water residues containing from less than .1 to 60 parts per million of nitrogen as nitrate.

In water residues containing over 50 parts per million nitrogen as nitrates traces of picric acid detectable by microchemical methods may be formed in the cold, but traces only.

Water residues heated in contact with phenoldisulphonic acid yield traces of picric acid, but only traces, unless the heating is long continued and the quantity of nitrate high, when appreciable amounts of picric acid may be formed.

Alkali salts of phenoldisulphonic acid occlude sufficiently large amounts of the alkali salts of nitrophenoldisulphonic acid to so color them and so modify their crystal form as to simulate in appearance and behavior another nitro compound.

THE MERCURY CATHODE IN RAPID ELECTROANALYSIS.

BY W. S KIMLEY.

Received October 8, 1909.

Mercury is superior to platinum for a cathode in several electroanalytical determinations; in some others there is no decided choice, and in several others there is no substitute for the platinum cathode. Some metals can be determined by using a mercury cathode, in an electrolyte that would not give a quantitative deposit on platinum in that the metal seems to be withdrawn from the solvent action of the electrolyte to a certain extent, *e. g.*, copper may be deposited from a solution containing 10 per cent. of nitric acid to within 0.05 per cent. by use of a mercury cathode, while with platinum it would be difficult to recover over 98–99 per cent. With some other metals mercury is superior because it will amalgamate with metals that would not always adhere well to platinum.

The method of H. Filippo,[1] in which the method of Kollock and Smith is modified to obviate working with small volumes, is to place an accurately weighed quantity of mercury in a round-bottomed flask, into the bottom of which is fused a platinum wire which barely projects through the glass and makes connection with the mercury.

---

[1] Leiden Univ., *Chem. Weekblad*, 6, 2269.

When the electrolysis is finished the amalgam is washed with water and alcohol and is poured into a weighing bottle half filled with alcohol. The alcohol is then removed with a pipette and a strip of blotting paper and the mercury is dried and weighed.

This method is open to criticism for several reasons. First, the end of the wire would closely hold a small drop of the amalgam and give low results. Second, although clean mercury can be easily transferred from one dish to another without loss, it would be difficult with many of the amalgams. Mercury loses some of its physical properties when it is alloyed with other metals. The meniscus loses its characteristic convex shape and even becomes concave in some instances.

The following method, originated by the author, is easy of accurate manipulation and will give satisfactory results with those metals to which the mercury cathode is adapted, and it also avoids working with the small volume used by Kollock and Smith. A platinum wire is sealed into the bottom of a round-bottomed fat flask weighing about 25 grams and holding about 125 cc.; 40 grams of mercury will cover the bottom of the flask and the outfit will weigh about 65 grams. When the deposition is complete the solution is siphoned off as far as possible without breaking the circuit, the flask filled with distilled water, and this repeated until the current drops nearly to zero. The flask is then removed from the stirrer and the liquid removed by a glass tube drawn out to a point like the tip of a wash-bottle, and attached to the suction pipe of a filter pump by a rubber tube. When the liquid is nearly all out, the flask is slightly tipped and a bare spot will appear where the tip can be placed against the glass and the last drop of water removed. By this method over 98.5 per cent. of the liquid can be easily withdrawn. After thoroughly washing with water, wash three times with alcohol, removing it in the same way except that it is caught in an empty wash-bottle and distilled over quicklime, when a sufficient quantity has accumulated. The amalgam is then washed once with ether and dried in a hot water oven until there is no odor of ether or alcohol, the flask being removed at intervals of one minute and the vapor blown out.

When it is easy to keep the volume small a convenient cell for the electrolysis can be easily made by placing the mercury in a common straight-sided weighing bottle holding about 60 cc. and making the connection by a platinum wire sealed in a glass tube reaching to the bottom and bent at the top so it nearly touches about half way up (Fig. 1). This keeps the tube at one side of the dish so that it does not interfere with the stirrer. The amalgam is washed and dried as before. In making the tube for connecting with the mercury, the wire is sealed in one end of the tube and the tube is then bent into shape and the other end is sealed so that no moisture may gather in the tube.

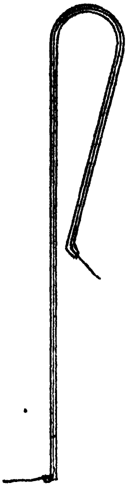

Fig 1.

In using the above cells they should be washed and dried the same before electrolysis as after, to obtain two weights under the same conditions.

The method of connecting with the mercury cathode through the glass tube is not considered superior to sealing a wire in the bottom of the weighing bottle, but it is easily prepared and avoids breaking an expensive piece of apparatus in some subsequent heating or cooling. The same method might be conveniently adapted to connect with the mercury in the round-bottomed cathode chamber (Fig. 2).

Because some of the metals exert a certain influence on others when they are present together, the following experiments were made on the determination of mixtures made by weighing out portions of chemically pure metals and dissolving them together.

A mixture containing, copper 85, lead 5, zinc 5, and tin 5 per cent., was dissolved in nitric acid (sp. gr. 1 20), evaporated nearly dry, diluted with water, boiled, allowed to stand a few minutes, and the precipitate, containing the tin and small amounts of copper and lead, was filtered off and fused with equal parts of sodium carbonate and sulphur in a small covered porcelain crucible. The fused mass was then dissolved in hot water and enough sodium sulphite added to reduce the polysulphides and so render the copper and lead sulphides insoluble. The tin in solution was filtered off and the insoluble sulphides dissolved in nitric acid and returned to the first filtrate, which measured less than 100 cc. This was then placed in the first described cathode chamber, previously prepared and weighed. The anode was of the disc form and was also weighed before attaching to the rotator. The anode was run very slowly to avoid detaching any of the lead peroxide. After starting the rotator the current was turned on and 15 cc. of nitric acid added. The lead separated on the anode and after washing with water, alcohol, and ether, was dried for 1.5 hours at 190° and weighed as peroxide.

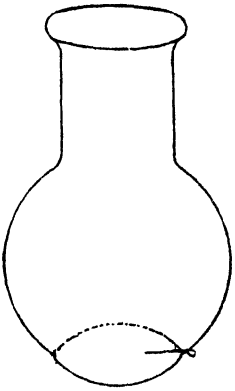

Fig. 2.

The copper separated and formed an amalgam, and after washing and drying the gain in weight of the cathode chamber gave the weight of the copper.

The solution and washings from the determination of lead and copper were run into a casserole, 0.5 cc. of sulphuric acid added and evaporated to fumes to drive off the nitric acid. The residue was then dissolved in a small amount of water and a few drops of sulphuric acid, if necessary. The acid was then neutralized with ammonia and an excess of 0.2 cc. of sulphuric acid added, then placed in the mercury cathode chamber made from the weighing bottle and electrolyzed for zinc. To the solution containing the tin was added 5 cc. of strong sodium hydroxide, 10 cc. of concentrated sodium sulphide solution and 20 grams of ammonium sulphate. It was then digested on the water bath for an hour and the tin deposited, using a platinum dish as a cathode, small amounts of ammonium sulphide being added as necessary to keep the sulphides in solution.

The accompanying table gives some of the results:

Constituent.	Voltage.	Amperes.	Time. Min.	Amount of metal present. Per cent.	Amount of metal found Per cent.	Per cent error.
Copper	5	2	120	85.00	84.98	—0.02
Lead	5	2	120	5.00	5.04	+0.04
Zinc	10	2	90	5.00	5.00	0.00
Tin	6½	2½	120	5.00	4.97	—0.03
				Total,	99.99	
Copper	5	2½	120	85.00	84.97	—0.03
Lead	5	2½	120	5.00	5.03	+0.03
Zinc	10	2	45	5.00	5.01	—0.01
Tin	6½	2½	180	5.00	4.97	—0.03
				Total,	99.98	

In the two following experiments the copper was deposited on platinum foil, other conditions remaining the same.

In the first one, 15.82 per cent. of copper was precipitated on the foil in 120 min., leaving 69.18 per cent. of copper not recovered, and in the second one 18.09 per cent. of copper was precipitated in 150 min., leaving 66.91 per cent. not recovered.

The solutions containing the remainder of the copper were each neutralized with ammonia, made just slightly acid with nitric acid and 0.2 cc. of sulphuric acid added, and the rest of the copper was recovered to within an error of 0.03 per cent. in the first and 0.07 per cent. in the second.

The above does not show that mercury is superior to platinum for the determination of copper, but it indicates that it is better when copper must be determined from a strongly acid solution, as is the case when the separation from lead is made; otherwise the gauze or foil is handier, as it is easier to wash and dry.

To illustrate the working of the process, the results of the analysis of two commercial alloys are given. The copper and zinc were deposited in mercury, the copper in the cathode chamber made from the round-bottomed flask and the zinc in one made from a straight-sided bottle. The results in No. 1 were checked by another chemist who got practically the same results, and in the case of the zinc exactly the same.

	No. 1. Per cent	No. 2. Per cent.
Copper	81.18	83.72
Lead	4.76	5.34
Zinc.	10.04	8.61
Tin	3.40	2.43
Iron	0.63	
	100.01	100.10

It has been stated by Price, *Journal of the Society of Chemical Industry*, that a mercury cathode gives low results with zinc on account of small particles of the amalgam being detached and lost during the process of washing, but by the above method of washing and drying there is apparently no loss, as in nearly every determination on known amounts of zinc the weight of the amalgam indicates at least the whole amount of zinc and in many instances from one- to three-tenths of a milligram more, which is probably due to a slight oxidation of the zinc while drying. Zinc is one of the metals that is best determined as an amalgam, for when deposited on platinum it is difficult to remove without rendering the platinum black and spongy.

Trials with antimony were unsuccessful, as the antimony formed on the surface of the mercury as a black powder and some became lost in washing.

Tin in solution as sulphate forms an amalgam but as yet has given low results.

Several mixtures were made by dissolving copper 0.50, lead 0.35, zinc 0.10 and tin 0.05 gram, and analyzed the same as before, except that the bulk of the lead was precipitated as sulphate and filtered on a Gooch and weighed as sulphate. The small amount remaining was electrolyzed and weighed as lead peroxide and the two added together. This has been found by numerous experiments to give the best results when dealing with comparatively large amounts of lead, as if all the lead is deposited as peroxide the results will be high.

In these mixtures of metals the largest percentage error was 0.04 per cent.

The above described mercury cathode chambers have been placed in the hands of inexperienced persons for the determination of copper, nickel, and zinc, and after a few trials they have been able to get results equally as accurate as the ones recorded above.

[CONTRIBUTIONS FROM THE HAVEMEYER LABORATORIES, COLUMBIA UNIVERSITY, No. 176.]

THE VOLUMETRIC DETERMINATION OF CERIUM IN CERITE AND MONAZITE.

BY F J METZGER AND M HEIDELBERGER

Received March 16, 1910

In a previous number of THIS JOURNAL[1] it was shown by one of us that cerium could be accurately and rapidly determined in the presence of other rare earths by oxidation of the sulphate in sulphuric acid solution with sodium bismuthate, reduction of the ceric salt with an excess of ferrous sulphate, and titration of the excess of ferrous sulphate with potassium permanganate. This method has now been applied with excellent results to the analysis of cerite and monazite sands, and has also been used, with certain modifications, for the determination of cerium in mantle ash, in connection with a colorimetric method for the latter now being worked out in this laboratory. The results on mantle ash are withheld until the completion of this method.

The solutions required for the determination of cerium in cerite and monazite are: (1) A potassium permanganate solution, approximately *N*/40. It was found necessary to standardize this solution at least every two weeks, as it deteriorated slowly in spite of all precautions, presumably owing to the extent of dilution. (2) A solution containing 10 grams of Mohr's salt and 50 cc. of concentrated sulphuric acid per liter. This solution should be standardized every time it is used. The value of the permanganate in terms of iron, multiplied by 3.08415, gives its value in terms of CeO_2 (1910 at. wts.).

In the case of the cerite, 0.5 gram of the finely powdered mineral was fused with potassium bisulphate, and the melt dissolved in about 350 cc. of cold water acidulated with not more than 5 cc. of concentrated sulphuric acid. Care must be taken, in making the fusion, not to allow a ring of finely divided, undecomposed cerite to form on the side of the crucible around the top of the fused mass, otherwise fusion of the residue may be necessary. The solution must also be left in contact with the residue overnight, or until all basic salts which may have formed are dissolved.[2]

The monazites (0.6 gram samples) were decomposed in the usual manner, by heating on a hot plate in small porcelain dishes with concentrated sulphuric acid for at least six hours, the mixtures being stirred occasionally. They were then carefully poured into about 350 cc. of ice-cold water and allowed to stand overnight, or until all basic salts had dissolved.

---

[1] THIS JOURNAL, 31, 523.

[2] When these conditions have been carefully followed, further treatment of the residue is unnecessary.

The cerite and monazite solutions were then filtered, heated to boiling, and the rare earths precipitated by the addition of a large excess (100 cc. or more) of a saturated solution of oxalic acid. After standing overnight, the precipitated oxalates were filtered off and washed with a 1 per cent. solution of oxalic acid. It had been expected that the sulphuric acid solution of the sample could be treated directly wth sodium bismuthate without removal of impurities, but the separation of the rare earths as oxalates was found necessary owing to the discovery that manganese interfered, giving high results. Experiments now under way in this laboratory indicate that the manganese is held in solution apparently in the quadrivalent form, and a volumetric method for its determination is now being worked out.

Three general methods suggested themselves for the treatment of the oxalate precipitate:

1. It may be washed off the filter paper with water, dissolved with 20 cc. of concentrated sulphuric acid, and, after the addition of 5 grams of ammonium sulphate and dilution to 100 cc., oxidized by means of 2 grams of sodium bismuthate. This method was successfully used in analysis 5*a*, but could not be applied to 1, as it was found in one case that enough basic salts were precipitated to hold back some cerium, while in another case an excessive amount of bismuthate had to be used, resulting in a very heavy precipitation of basic salts. While this method cannot, in general, be recommended, it is believed that it will give satisfactory results when the precipitate of oxalates is small, and care is taken to avoid the introduction of organic matter from the filter paper, preferably by the use of hardened papers.

2. The precipitate and paper may be transferred to a platinum crucible and ignited, finally with a blast lamp. The mixed oxides are then warmed in the crucible for several hours with 10 cc. of concentrated sulphuric acid, allowed to cool, and carefully poured into about 100 cc. of cold water. It was found that incomplete solution results, even on long standing, but on the addition of 10 cc. more of concentrated sulphuric acid, and subsequent evaporation on a hot plate, a clear, yellow solution is obtained. This is diluted to 100 cc., 2 grams of ammonium sulphate added, and oxidation effected by means of 1 gram of sodium bismuthate. This method was used with good results in analysis 9.

3. The oxalates may be washed off the filter with hot water and converted to hydroxides by boiling with sodium hydroxide. The precipitate is filtered off, washed well with hot water, and dissolved through the filter by means of dilute sulphuric acid. The filtrate is diluted to 100 cc. after adding enough sulphuric acid to bring the amount up to 20 grams of the concentrated acid. Ammonium sulphate and sodium bismuthate are then added as in method 2. Method 3 was used for

all the analyses except those mentioned above. While not as rapid as method 1, it was found to be entirely trustworthy, and in addition proved itself far more convenient and rapid than 2. It is therefore recommended as the best of the three methods.

In all the determinations, after adding the sodium bismuthate, the solution was slowly brought to the boiling point, allowed to settle a moment, and then decanted from the residue through a gooch. The residue must be thoroughly washed with 2 per cent. sulphuric acid in order to remove all the cerium. The filtrate is then titrated with the ferrous sulphate solution until an excess has been run in, the excess being titrated back with the permanganate solution.

Duplicate determinations were made on each sample with the following results:

No.	Material.	Source.	Per cent CeO_2.
1a	Cerite	Unknown	22.08
1b			21.97
2a	Monazite	Brazil	28.60
2b			28.74
3a	Monazite	Brazil	22.84
3b			22.56
4a	Monazite	Brazil	23.13
4b			23.16
5a	Monazite	Brazil	23.93
5b			24.01
6a	Monazite	Brazil	27.25
6b			27.09
7a	Monazite	Brazil	24.31
7b			24.28
8a	Monazite	North Carolina	22.19
8b			21.99
9a	Monazite	North Carolina	22.54
9b			22.49
10a	Monazite	North Carolina	20.47
10b			20.55

The above results show that the new volumetric method for cerium yields accurate results when applied to monazite and cerite. In addition to its accuracy, the method recommends itself on account of its ease of manipulation and its rapidity.

QUANTITATIVE LABORATORY.

THE REACTION BETWEEN HYDRIODIC ACID AND BROMIC ACID IN THE PRESENCE OF A LARGE AMOUNT OF HYDROCHLORIC ACID.

BY D. L. RANDALL.

Received March 11, 1910.

Andrews[1] has shown that when a solution of potassium iodide, strongly acidified with hydrochloric acid, is titrated with a standard solution of potassium iodate the reaction takes place according to the following equation:

---

[1] THIS JOURNAL, 25, 756.

$$2KI + KIO_3 + 6HCl = 3KCl + 3ICl + 3H_2O$$

When a small amount of chloroform is present the completion of the reaction can be very easily recognized by the fading of the violet color in the chloroform and the amount of iodide present accurately determined from the quantity of iodate used. Andrews also used this method for the determination o' free iodine, chlorates, chromates, arsenites and ferrous salts.

At the summer meeting of the American Chemical Society, at Detroit, it was mentioned that very few uses were now made of bromates, in spite of the fact that the salts of bromic acid can easily be made in a condition of great purity. It seemed possible that potassium bromate might be substituted for the more expensive potassium iodate for the determination of the iodides and the other substances worked upon by Andrews.

Experiments were made in which standard potassium bromate solution was added to potassium iodide in a solution that contained about fifty per cent. of strong hydrochloric acid, and it was soon found that a less amount of potassium bromate solution was used than that required by the equation

$$2KI + KBrO_3 + 6HCl = 3KCl + 3H_2O + 2ICl + BrCl.$$

The amount of bromate used was almost exactly two-thirds the quantity required by the above equation. That seemed to indicate that three molecules of potassium iodide instead of two were oxidized by one molecule of bromate, so that the reaction probably goes as follows:

$$3KI + KBrO_3 + 6HCl = 4KCl + 3H_2O + 2ICl + IBr.$$

That the bromate and iodide act in this way is shown by the experiments in which the following solutions were used:

1. A standard solution of potassium bromate made by dissolving 5.5673 grams of the recrystallized salt in one liter of water.
2. An approximately tenth-normal solution of potassium iodide prepared by dissolving 16.607 grams of the commercial C. P. salt in a liter of water.
3. An approximately tenth-normal solution of sodium thiosulphate.

The sodium thiosulphate solution was standardized by treating a known amount of the standard bromate solution with two grams of potassium iodide and five cc. of concentrated hydrochloric acid and titrating the iodine set free with the thiosulphate. The strength of the potassium iodide solution was determined by treating 20 cc. of the iodide solution in a distilling flask with an excess of ferric alum and 5 cc. of sulphuric acid (1 : 1) and distilling over the iodine set free into potassium iodide solution and titrating with the thiosulphate.

In each of the following experiments 20 cc. of the potassium iodide solution in a 250 cc. glass-stoppered bottle were treated with different amounts of hydrochloric acid and five cc. of chloroform. The bromate solution was run in until, after violent shaking, the chloroform had lost its pink color. The results obtained are given in the following table:

A.

KI soln cc	HCl (1 . 1) cc	H_2O cc	$KBrO_3$ soln cc.	I taken. Gram.	I found. Gram	Error.
20	40	0	19.92	0.2523	0.2530	+0.0007
20	30	10	19.94	0.2523	0.2532	+0.0009
20	20	20	20.00	0.2523	0.2539	+0.0016

B.[1]

KI soln cc	Conc HCl. cc	H_2O. cc	$KBrO_3$ soln. cc	I taken Gram.	I found. Gram	Error.
20	40	0	19.87	0.2508	0.2523	+0.0015
20	40	0	19.87	0.2508	0.2523	+0.0015
20	40	0	19.81	0.2508	0.2516	+0.0008
20	20	20	19.87	0.2508	0.2523	+0.0015
20	30	10	19.90	0.2508	0.2527	+0.0019
20	40	0	19.80	0.2508	0.2514	+0.0006
20	40	0	19.85	0.2508	0.2521	+0.0013
20	40	0	19.80	0.2508	0.2514	+0.0006

In all cases a slight positive error could be observed, probably due to the fact that the end point was less sharp with the iodine and chloroform than with the starch iodine indicator.

If a bromide is substituted for an iodide, while a reaction takes place and the chloroform is colored, still complete bleaching is not obtained even by adding an excess of the bromate, so we cannot determine in this way what reaction takes place between bromides and bromates in the presence of strong hydrochloric acid. With ferrous salts there is no coloration of the chloroform at all.

Summary.

This work has shown that like the iodate the bromate will oxidize the iodide, but the bromate is a more powerful oxidizer in that the bromine itself will react with one atom of iodine. Further, iodides may be easily and rapidly determined by titrating the iodide solution with standard bromate solution in the presence of twice its volume of hydrochloric acid.

COMPOSITION OF SEA WATERS NEAR BEAUFORT, NORTH CAROLINA.

By Alvin S. Wheeler.

Received February 25, 1910.

Clarke, in his "Data of Geochemistry," reports no analyses of sea waters along the coasts of North America. Possibly no careful analyses have been made. These analyses were undertaken owing to the increasing interest which biologists are taking in the chemical composition of sea water as a feature of the environment of sea life. The work was done during the summer of 1909 at the U. S. Biological Laboratory at Beaufort, North Carolina, and for the U. S. Bureau of Fisheries. I wish to express here my thanks to the Commissioner of Fisheries, Mr. George M. Bowers, for his courtesy in permitting the publication of my report.

---

[1] Solutions of different strengths than those used in A were taken.

Sodium and Potassium.—The most careful investigation of sea water was made by Dittmar, reported in the "Report of the Scientific Results of the Exploring Voyage of H. M. S. Challenger, 1873–1876," Vol. I, Physics and Chemistry. This work was not at hand when this investigation was undertaken and the usual methods for determining sodium and potassium were adopted These are given in "Mineral Waters of the United States," *Bull.* 91, Bureau of Chemistry, by J. H. Haywood and B. H. Smith. The determination of sodium came out low, the total bases being insufficient for the total acids. This experience is in agreement with the statement of Dittmar that "the routine method adopted in mineral salt analysis, *i. e.*, the elimination of lime and magnesia and subsequent joint determination of soda and potash as sulphates or muriates, would never give sufficiently precise results." My determinations were therefore corrected by employing Dittmar's method of "total sulphates." Ten cubic centimeters of water were weighed out in a glass-stoppered weighing bottle and evaporated to dryness in a platinum dish with a small excess of sulphuric acid, a dilute solution of known strength being employed. After evaporation to dryness over steam, the residue was heated on a sand bath and finally ignited to dull redness to constant weight. The following figures show the value of the method. The values for sodium sulphate by the total sulphate method and by calculation from the determinations of the other constituents differed by two parts in a thousand. On the other hand, the values obtained experimentally, after elimination of sulphuric acid, lime and magnesia, and by calculation from the determinations of the other constituents, differed anywhere from thirteen to thirty in a thousand.

Calcium and Magnesium.—Forty cubic centimeters of water were weighed out and transferred to a beaker. One cc. 5 *N* hydrochloric acid was added and the mixture boiled to expel carbon dioxide. After cooling, four cc. 5 *N* ammonium hydroxide and five cc. *N*/2 ammonium oxalate solution were added. The next day the supernatant liquid was decanted upon a filter, the residue redissolved in dilute hydrochloric acid and reprecipitated with ammonium hydroxide and a little ammonium oxalate solution. The following day the calcium oxalate was filtered upon the filter already used, washed with hot water and ignited in a platinum crucible to constant weight. The combined filtrates were concentrated to a volume of 150 cc., cooled, mixed with ten cc. normal disodium phosphate solution and ten cc. strong ammonium hydroxide. The next day the precipitate was filtered off, washed with dilute ammonium hydroxide and finally with water. It was ignited in an open platinum crucible.

Chlorine.—Eight cc. sea water were weighed out and transferred to a beaker. Titration was conducted with a standard solution of silver nitrate (one cc. = 0.003555 gram Cl), using potassium chromate as indicator. In order to better observe the change of tint, a standard of comparison was made by precipitating a sodium chloride solution with excess of silver nitrate and re-establishing the yellow color with a little more salt. The silver nitrate solution was standardized by means of two samples of sodium chloride: 1. A sample labeled "Sodium Chloride, C. P., Eimer and Amend" was dissolved in pure water and reprecipitated with hydrochloric acid. It was filtered off, washed with water, and ignited. 2. A sample labeled "Sodium Chloride, C. P. Special. Baker's Analyzed Chemicals." The impurities were CaO = 0.001 per cent., Fe = 0.0001 per cent., SO_3 = 0.001 per cent.

Sulphuric Acid.—To 25 cc. sea water, which had been weighed, were added, while hot, 2 cc. dilute hydrochloric acid and 3 cc. *N* barium chloride solution. The next day the barium sulphate was filtered off, washed with hot water and ignited in a platinum crucible.

Carbon Dioxide.—The determination of carbon dioxide was carried out by titrating 100 g. of water with 0.05 *N* hydrochloric acid, using phenolphthalein as indicator for normal carbonates and then methyl orange for bicarbonates. The results were checked by titrating with 0.05 *N* acid potassium sulphate as recommended by Cameron.

Specific Gravities.—The specific gravities were determined by the use of a pycnometer of U-form. The temperature employed was that of the laboratory, in order to avoid the unusual condensation of moisture on the pycnometer if lower temperatures were used.

The Waters.—Five samples of water were analyzed. The localities were marked upon a chart of Beaufort Harbor which accompanies my report to the Bureau of Fisheries: *A*. Taken in Beaufort Inlet. *B*. At the laboratory dock where water is taken for the laboratory aquaria. *C*. In Bogue Sound, opposite Moorehead, where *Toxopneustes* are abundant. *D*. At a point between the eastern end of Beaufort and Bird Island shoal. *E*. At Green Rock, in Newport river, near the entrance to Core Creek.

The results are given below in four tables. Comparison is made with Dittmar's results. Challenger water No. 924, a deep sea water, is given in three tables, because this is the only water whose composition is reported in parts per thousand of water. It does not, of course, represent the average. For example, the value for chlorine is 55.396 per cent. of the total salts whereas the average for the 76 analyses is 55.420. Comparison is also made with the analysis of a water mentioned in an article by Curt Herbst in *Archiv fur Entwickelungs mechanik der Organismen*, **5**, 651. This water is from the Mediterranean sea below Naples, Italy.

APPARATUS FOR DRYING FLASKS, ETC.[1]

By Charles Baskerville and Reston Stevenson.

Received February 19, 1910

The frequent requirement in chemical work for dry flasks, bottles, test tubes, cylinders, beakers, etc., suggested the construction of a drying apparatus. Many forms of such an apparatus were devised, made, tried and found unsatisfactory. Then an electrical drier was constructed, about fifteen various forms were tried, and finally the form as presented in this paper was adopted as satisfactory. It is shown in Fig. 1.

The air enters the side tube *A* near the bottom, is heated by the red hot platinum wire *B* at the top of the apparatus, and the hot air which streams out dries the vessel which is placed over the top of the tube.

The air, before entrance, should be dried and cleaned by passing through sulphuric acid, calcium chloride, and cotton wool, so that the flask is dried more quickly and is cleaner than if ordinary air from the laboratory or from pipes were used. Compressed air is the convenient source of the air, but a foot-bellows is sufficient to operate the apparatus.

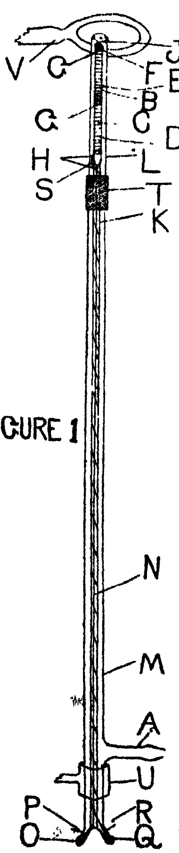

FIGURE 1

The heating is done by means of platinum wire *B*, wound around a porcelain tube *C*. If this platinum wire were the same gauge throughout its entire length, it would be dark at the bottom of the porcelain tube where the air first meets the platinum wire, dull red at the middle of the tube, white-hot at the top of the tube where the air which meets the platinum wire is already heated, and the length of wire which passes back through the center of the porcelain tube away from the air would fuse. This unequal heating, due to the different rates of radiation, can be avoided by constructing the heating wire by winding 10 inches of platinum wire of diameter 0.0115 inch around the lower part of the porcelain tube; 15 inches of diameter 0.013 inch around the middle and upper part of the tube; and 10 inches of diameter 0.14 inch around the top of the tube and back through the opening in the center of the tube. Also the windings are spaced unequally; the wires of diameter 0.0115 and 0.013 are wound closely at the lower part and farther apart at the upper part of the porcelain (see Figs. 1 and 2). In this way there are about 19 turns of diameter 0.0115 inch (see *D*), 25 turns of 0.013 (*E*), and 4 turns of 0.014 (*F*). By this arrangement, during use, the platinum coil glows with nearly uniform brightness throughout its length, so that the maximum efficiency is obtained with minimum weight of wire and minimum length of porcelain tube.

---

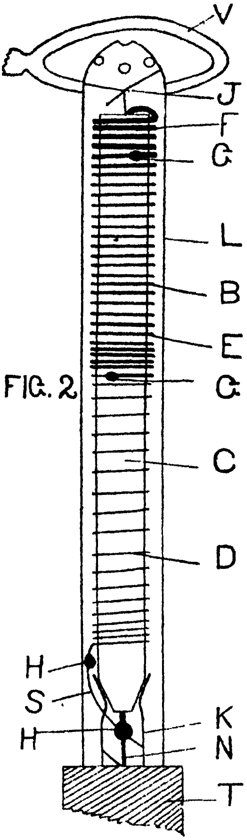
[1] Read before the New York Section, American Chemical Society, Dec. 17, 1909.

The platinum wires are joined to each other autogenously (*G*,*G*) in the flame of the gas-oxygen blast lamp. The platinum wires are joined to the copper wires (*N*,*S*) autogenously in the flame of the air-gas blast lamp. These joints (*H*,*H*) are strong and neat.

The porcelain tube *C* is 2¾ inches long, of diameter 0.15 inch, and has an opening through its center of 0.035 inch diameter. Into the hole at the top enters a platinum wire, *J*, which has at its top 3 radiating platinum wires (the 4 wires are readily joined together at the same point in the flame of the gas-oxygen blast lamp). These wires reach out to the hard glass tube *L* and prevent the red hot platinum wires from touching and cracking the glass tube. The lower end of the porcelain tube is beveled and rests in the flared end of the soft glass tube *K*, which rests upon the bottom of the soft glass tube *M* and supports the porcelain tube.

Through the tube *K* goes the copper wire *N* of diameter 0.02 inch. This wire is sealed into the tube at *O* with blue enamel glass and presents a terminal at *P*. The external portion of the wire is wound around the tube several times in order to prevent breaking at *O*. The other copper wire, *S*, is wound around the glass tube *K*, whereby short-circuiting with wire *N* is prevented. The other terminal is at *R*. These copper wires do not get hot and do not appreciably oxidize.

FIG. 2



The tip *L* is made of hard glass. It can be readily removed from the rest of the apparatus, disengaging it at the rubber tube *T*, so that broken tips can be replaced or other forms of tips can be substituted within a few seconds. The form of tip shown in Figs. 1 and 2 has six small holes at the top, which sprinkle the effluent air in every direction and is the best form for most uses, although various shapes can be made for special purposes.

Between the terminals *P* and *R* there is a resistance of about 5 ohms, and a current of about 6 amperes is requisite to heat the platinum wire to bright redness, so that the apparatus operates with a 30-volt current. In order to cut down a 110-volt current, about 50 cents worth of German silver wire, No. 22, will be sufficient. The entire length of the apparatus is about 30 inches. It is supported by a clamp, *U*, attached to an iron stand. Also attached to this stand is a ring, *V*, which supports the flask over the drier at an adjustible height.

The temperature of the current of air at a distance of an inch from the tip is about 100°.

In the operation of the dryer, the precautions must be taken that in starting, the current of air should be turned on before the current of electricity; and in stopping, the electricity should be turned off before the air.

The advantages of this form of drying apparatus are—

1. The heat is supplied just before the air enters the flask, so that there is no time given for the air to cool off before it reaches the moisture.

2. The air is both hot and dry, and is blown in all directions forcibly against the walls of the vessel which is to be dried, so that the operation is rapid. Furthermore, the temperature is not high enough to produce hysteresis of standard apparatus.

3. There is no necessity for the use of alcohol and ether, and the air which reaches the flask is free from dust, oil, etc., so that the flask is clean when it is dry.

This apparatus has been in practical use several months in the physical chemistry laboratories of the College of the City of New York, for drying bottles, flasks, test tubes, cylinders, beakers, etc., and has been found rapid, effective and convenient. This apparatus, apart from the external resistance, may be ordered from Eimer & Amend, at a cost of about $6.00.

ANALYSIS OF SOME BOLIVIAN BRONZES.[1]

By MORRIS LOEB AND S. R MOREY

Received February 26, 1910.

Through the kindness of the authorities of the American Museum of Natural History, we were enabled to analyze portions of certain implements collected in the region around Lake Titicaca. It will be seen that these metals differ remarkably in composition, and indicate the possession of considerable metallurgical skill by the inhabitants of that region. The absence of the slightest traces of silver may be taken as a proof that the tin was derived from cassiterite, rather than native tin. The composition of Specimen IV suggests its preparation from domeykite, or some other copper arsenide, fairly free from sulphur. Owing to the small mass of samples, which were drilled or cut from the specimens, the density determinations, made with water in a pycnometer, are only approximate. In Specimen VI the porosity of the material undoubtedly occasioned a low result. Tin and copper were separated by potassium polysulphide, the former determined as stannic oxide and the latter electrolytically. Arsenic was separated from copper by Crookes' method, and sulphur was weighed as barium sulphate after oxidation with nitric acid in a sealed tube.

[1] Average of two complete analyses.

[2] Average of three concordant analyses.

[1] Presented at the Second Decennial Celebration of Clark University, Worcester, Mass., September 16, 1909.

ΔC_p	Decrease in molecular heat capacity attending a change in state of aggregation.
(1) K_C, (2) K_N	Equilibrium constant in terms of (1) volume concentrations, (2) mol fractions. (Products of the reaction in the denominator.)
K_S	Solubility product in terms of mol fractions.
(1) L_S (2) L_v (3) L_F	Molecular heat of (1) sublimation, (2) vaporization, (3) fusion (under constant external pressure).
(1) N, (2) N'	Mol fraction of (1) solvent, (2) solute.
(1) n, (2) n'	Number of mols of (1) solvent, (2) solute.
p	Gas or vapor pressure.
P	External pressure on a liquid or solid.
Q_π	Heat evolved when the reaction $a\text{A} + b\text{B} + \ldots = m\text{M} + n\text{N} + \ldots$ takes place from left to right in a solution under osmotic equilibrium.
R	Gas constant.
(1) T, (2) T_F, (3) T_O, (4) T_B, (5) T_{Bo}	(1) Absolute temperature, (2) absolute temperature of the freezing point of a solution, (3) of the freezing point of the pure solvent, (4) of the boiling point of a solution, (5) of the boiling point of the pure solvent.
U	Total energy decrease produced when the reaction $a\text{A} + b\text{B} + \ldots = m\text{M} + n\text{N} + \ldots$ takes place from left to right
(1) v, (2) V	Molecular volume of (1) a gas, (2) a liquid.
π	Osmotic pressure.
μ	Thermodynamic potential.
ψ	Fugacity.
ξ	Activity.

I. The Development of the Modern Theory of Solutions.

Upon the foundations laid by the labors of van't Hoff and Arrhenius has arisen the structure which we know to-day as the Modern Theory of Solutions. Before van't Hoff's epoch-making discovery of the thermodynamic relations which bind together the colligative properties[2] of dilute solutions, our knowledge concerning these important quantities was confined to a set of apparently unconnected empirical laws. Van't Hoff's generalization of these laws, followed almost immediately by the Ionic Theory of Arrhenius, stimulated greatly the study of solutions and made possible the rapid development and perfection of our present theory. Investigation has, however, been confined chiefly to the domain of dilute solutions and the Modern Theory of Solutions has remained almost entirely a theory of dilute solutions. The reason for this is, I believe, due largely to one of those historical "accidents" which occur now and then in the development of science. The history of this "accident" and the manner in which it came about forms a chapter in physical chemistry of interest alike to the chemist and to the philosopher.

Perhaps the best way to form a clear idea of the process of evolution of our present theory of solutions is to consider first the colligative properties of solutions and the relations which connect them. These quantities—the osmotic pressure, vapor pressure, freezing point, boiling point, etc.—have played such an important and vital part in the development of our solution theory that a clear idea of their relations to one another is absolutely essential to a proper understanding of the theory and of its development. The nature of these relations is expressed by the following statement: *The colligative properties of a solution are connected by a set of rigorous differential equations which involve no assumptions except the two laws of thermodynamics.* The equations are as follows:

---

[2] Following Ostwald, the term "colligative properties" is used to embrace such properties as osmotic pressure, boiling point raising, freezing point lowering, vapor pressure lowering, etc.

(1) Osmotic Pressure and Freezing Point,

$$d\pi = \left(\frac{-L_F}{V}\right)\frac{dT_F}{T_F}. \qquad (82)$$

(2) Vapor Pressure and Freezing Point,

$$dp = \left(\frac{L_S}{v}\right)\frac{dT_F}{T_F}. \qquad (92)^*$$

(3) Osmotic Pressure and Vapor Pressure,

$$d\pi = \left(\frac{-v}{V}\right)dp. \qquad (77)$$

(4) Osmotic Pressure and Boiling Point,

$$d\pi = \left(\frac{l_v}{V}\right)\frac{dT_B}{T_B}. \qquad (90)$$

To these should be added a number of others, such as the relation between the electromotive force of a concentration cell and either vapor pressure (74) or osmotic pressure (70), and (16 and 14) the mutual relations among the osmotic pressures or vapor pressures of the constituents of a physical mixture or (30 and 30*a*) the substances concerned in a chemical equilibrium, etc.[3] While the following discussion applies with equal force to all of these relations, it will perhaps be conducive to clearness, if we confine our attention chiefly to the four relations given above.

From the method of derivation of these relations, it is clear that they do not involve any assumptions regarding the concentration of the solution, nor do they depend in any way upon the nature of the dissolved solute or its degree of association, dissociation, or solvation. In fact, if one knows, for example, the vapor pressure, freezing point lowering or boiling point raising for a solution of any nonvolatile solute, he has the means of calculating the osmotic pressure for the same temperature without knowing either the concentration of the solution or the nature of the solute. There may be one or several solutes present and they may associate, dissociate, or unite with each other or with the solvent in any manner and to any extent. These questions are in no way involved in the calculation. Since relations such as those existing among the colligative properties of a solution involve only the two laws of thermodynamics, it will be convenient to refer to them as "*purely thermodynamic relations*," to distinguish them from an important group of relations which involve the composition of the solution and the nature of its components, and which we will now proceed to consider.

---

[3] The derivations of these relations and a more detailed discussion of them are given in a previous paper, "A Simple System of Thermodynamic Chemistry Based upon a Modification of the Method of Carnot" (THIS JOURNAL, 32, 467 (1910)). For convenience in reference these equations are given the same number here as in the previous paper where the significance of the quantities appearing in the equations is explained in detail.

Let us consider a solution of any solute A in any solvent B, and let our problem be to express each of the colligative properties of the solution as a function of its composition or its "concentration." This problem can in general be solved only by direct experiment for the particular solvent and solute under consideration. From what has preceded, however, it is evident that as soon as we know the relation between *any one* of the colligative properties and the composition of the solution, the other relations become thereby determined. If, for example, we determined the freezing point of the solution for a series of concentrations, we could calculate thermodynamically the osmotic pressure, the vapor pressure, etc., for the same concentrations and thus derive an equation connecting each of these quantities with the concentration. The colligative property which should be chosen for experimental study in a given case would depend upon the relative ease and accuracy with which the several quantities could be determined and the temperature range which it was desired to cover; also in some cases upon whether the requisite "caloric quantities"[4] were known with sufficient accuracy or could be determined readily.

The relation between any one of the colligative properties and the concentration of the solution for any given solvent and solute will obviously depend upon the degree of association, dissociation and solvation of the solute.[5] Since the magnitude of these effects and their dependence upon the concentration are in general unknown quantities, the problem is too complex for any complete solution. In general, therefore, it is necessary to make a separate investigation for every solvent and solute in order to establish the desired relation connecting some one of the colligative properties with the concentration. To leave the problem in this condition, however, is naturally not very satisfactory, and the course usually followed by science when confronted with a problem which is too complex is first to simplify the problem. Let us try to trace the process of simplification which has been followed by science in the present instance.

Since association or dissociation of either solvent or solute molecules introduces complications, the first step in the process of simplification is obviously to consider the simple case of a solution in which neither takes place. Since the union of a portion or all of the solute molecules with the solvent molecules (solvation) is also a complicating factor, the next step in the process of simplification would naturally be to eliminate this factor also by assuming no solvation. After making these simplifications our problem would read as follows: What are the relations connecting the colligative properties with the composition in the case of a solution in which the number of molecular species present is equal to the number of components?[6] Let us call such a solution, provisionally, an "ideal solution," postponing until later a more definite and accurate description of the properties of the type of solution to which the term "ideal" should be applied.

---

[4] Proposed by van der Waals to distinguish heat capacities, latent heats, heats of reaction, etc., from colligative properties.

[5] It is hardly necessary to remark that this statement tacitly assumes that the desired relation is to be one which involves the number of mols of the solute.

[6] For example, in the case of two components, a solvent and one solute, there would be only two different kinds of molecules; for a solvent and two solutes, only three different kinds of molecules, etc.

There is, however, another method by which the complicating factor of solvation can also be eliminated. Willard Gibbs, in his monumental work on thermodynamic chemistry, has taught us that the proper way to represent the composition of any phase is by the means of the mol fractions of its several components.[7]

Now in the case of a solution, the mol fraction of the solute (for example) will be altered if it becomes solvated on going into solution, owing to the consequent change in the number of solvent molecules. Such a complication can be eliminated from our problem, as explained above, by assuming no solvation; or it can be likewise eliminated *by taking the solution sufficiently dilute.* For, as the solution becomes more and more dilute, the limit approached by the mol fraction of the solute is the same whether solvation occurs or not.[8]

Owing to an "historical accident" the latter method of eliminating the complication of solvation has been the one followed by science, instead of the former and more logical one. The "historical accident"[9] in this instance was van't Hoff's brilliant discovery of the remarkably simple equation connecting osmotic pressure with temperature and concentration in very dilute solutions. Starting with this equation as a basis and using the principles of thermodynamics, he showed us how to construct a complete theory of dilute solutions.

As the field of dilute solutions became more and more developed, both from the experimental and theoretical side, investigators began to turn their attention to the subject of concentrated solutions. Investigation in this direction has usually taken the direction of attempts to extend the osmotic pressure equation by the introduction of quantities corresponding to the *a* and *b* of van der Waals' *condition equation* for gases, upon the basis of kinetic conceptions derived from an assumed analogy between osmotic and gas pressure. Other investigators have sought to attribute all of the deviation of concentrated solutions from the equations of dilute solutions, to solvation, and have even gone so far as to compute on this basis the approximate degree of hydration in some very concentrated aqueous solutions, for example. Still other attempts have been taken in the direction of an extension of our present equations by the addition of a series of terms containing a number of constants intended to express the influence of the solute molecules upon one another and upon the solvent.

---

[7] This system has been consistently followed by all investigators who use systems of thermodynamics based upon Gibbs' thermodynamic potential. The reason that it has not been followed by others is because they have confined themselves to the region of dilute solutions, where it is possible to use one of the limiting forms approached by the mol fraction of the solute, as the concentration approaches zero.

[8] To illustrate, if we put n' mols of a solute in n mols of a solvent and no solvation (or dissociation or association) occurs, then the mol fraction of the solute is $\frac{n'}{(n' + n)}$. If, however, on the average x mols of solvent are combined with each mol of solute, the mol fraction of the (solvated) solute is $\frac{n'}{[n' + n - n'x]}$ or $\frac{n'}{[n'(1-x) + n]}$. As the solution becomes more and more dilute, both expressions approach $\frac{n'}{n}$ as their limit. This is the familiar ratio which appears in our boiling point and freezing point equations. In the case of our osmotic pressure equation, instead of writing it $\pi = \left(\frac{n'}{n}\right)\left(\frac{RT}{V}\right)$, where V is the molecular volume of the solvent, it is customary to substitute $V_s = nV$ and write $\pi V_s = n'RT$. Here again, if the solution is *sufficiently* dilute, it is obviously immaterial whether we understand V_s to mean the volume of the solution or the volume of pure solvent in which the n' mols of solute were dissolved in preparing the solution.

[9] The expression, "historical accident," is, of course, used in the philosophical sense.

Attempts to obtain a satisfactory theory of concentrated solutions in any of these directions give no promise of success. An attempt to "explain" why, as a solution becomes more and more concentrated, it deviates more and more from the equations of very dilute solutions is somewhat analogous to an attempt to explain why the sine of angle, which for sufficiently small angles is equal to the angle, deviates more and more as the angle grows larger. The reason is, of course, a purely mathematical one. Similarly in the case of solutions there is first of all a purely mathematical reason why concentrated solutions should deviate from the equations of the infinitely dilute solution. The equations of dilute solutions are the limiting forms assumed by more general equations, owing to the fact that certain terms become negligible as the concentration approaches zero. In other words we have in our dilute solution laws only a portion, the residue, so to speak, of a more general set of laws for solutions of all concentrations. Consequently before science can hope to make any progress in the region of concentrated solutions she must go back to the point where the simplifying assumption of a dilute solution was unconsciously introduced, and, in place of it, make the simplifying assumption of an "ideal solution" as we have defined it above. We come, therefore, to

2. The Laws of the Ideal Solution.

Owing to the simplicity of the thermodynamic treatment of solutions by what we may call the osmotic-cyclical-process method and the fact that it uses conceptions which are comparatively easy to grasp and processes which can be readily pictured in the mind, it has been the favorite system among physical chemists. The fact that the theories developed by the advocates of this method have been confined almost entirely to the domain of the dilute solution is not due to any inherent fault in the method. In addition to this method we have the systems of thermodynamics based upon the Gibbs thermodynamic potential and its related functions. These systems have been the favorite ones among physicists and those who by training and inclination were accustomed to the use of potential functions, and it is among the advocates of the thermodynamic potential that we find the first successful attempt to formulate a theory of solution which is free from the assumption that the solution must be dilute.

This theory has been developed in Holland by van der Waals and his associates, especially by van Laar. The first attempt was made in 1893 by Hondius Boldingh[10] in an Amsterdam Dissertation which so far as I have been able to learn has never been published elsewhere. In the following year van Laar[11] published two papers in which he derived a set of "exact formulae for osmotic pressure, change in solubility, freezing point, boiling point, etc." His results were expressed in a series of equations in which the concentration of the solution appeared in a term, $\ln(1-N')$, in which N' represents the mol fraction of the solute. The equations contained, in addition, an undetermined function of the molecular thermodynamic potentials of the constituents. In numerous subsequent publications van Laar has advocated with great warmth and zeal, the use of the thermodynamic potential method and the introduction of the concentration of the solution into the equations by means of the expression $\ln(1-N')$, instead of assuming that the solution is dilute. Van Laar has in fact advocated a theory of solution which is entirely free from the assumption that the solution must be dilute. The foundations for this theory have existed in the literature for the last fifteen years. If it occurs to any one to wonder why the theory has not come into general use in the chemical world, he has only to glance through some of van Laar's papers, especially his earlier ones, and the reason will be more or less obvious.

---

[10] Boldingh, "De Afwijkingen van de Wetten voor Verdunde Oplossingen." Dissertation, Amsterdam, 1893.

It is my present purpose to free this theory from the language of the thermodynamic potential and to develop it in the so-called "osmotic language."[12] Stated in this language, our problem is to determine the functional relation between some one of the colligative properties of the solution and its concentration in the case of an ideal solution. Theoretically we can start with any one of the colligative properties we choose, but since our present theory of dilute solutions is usually assumed to start with the osmotic-pressure-concentration relation, it will perhaps be more interesting to develop our theory of the ideal solution from the same standpoint.

Let us, therefore, turn to the equation which expresses the osmotic pressure[13] for a very dilute solution:

$$\pi = \frac{n'RT}{V_s} = \frac{n'RT}{nV} \qquad (100)$$

In this equation, n' is the number of mols of solute in n mols of solvent and V is the molecular volume of the pure liquid solvent. Let us now make use of the method, introduced by Willard Gibbs, of expressing the composition of the solution by means of the equation $N' + N = 1$, where N' is the mol fraction of the solute and N that of the solvent. The above equation can now be written:

$$\pi = \frac{\frac{n'}{n+n'}RT}{\frac{n}{n+n'}V} = \frac{N'RT}{NV} \qquad (101)$$

---

[11] van Laar, *Z. physik. Chem.*, 15, 457 (1894).

[12] The "language of the colligative properties" would be a better term. Too much importance is usually ascribed to osmotic pressure in our solution theory.

[13] Throughout this paper, we shall understand by the term "osmotic pressure," the pressure difference π as defined by the equation $\pi = P - P_A$, where P_A is the pressure upon the pure liquid solvent A when it is in equilibrium (through a membrane or medium permeable only to itself) with the solution under the constant pressure P. This has been discussed more fully in the previous paper (THIS JOURNAL, 32, 478 (1910)).

We have long recognized the fact that our osmotic pressure equation expresses *strictly* only the limit approached by the osmotic pressure as the concentration of the solution approaches zero. Let us therefore write the equation itself so that it will indicate this fact. This gives us

$$\Delta\pi = \left(\frac{\Delta N'}{N}\right)\left(\frac{RT}{V}\right). \tag{102}$$

Seeing the equation in this form it is natural to suspect that the real relation might possibly be

$$d\pi = \left(\frac{dN'}{N}\right)\left(\frac{RT}{V}\right), \tag{103}$$

or since by definition—$dN' = dN$,

$$d\pi = \left(\frac{-RT}{V}\right) d \ln N. \tag{104}$$

Stated in words, this means that not only would the addition of dN' mols of solute to a pure solvent involve an increase (*i. e.*, from 0 to $\Delta\pi$) of osmotic pressure which satisfies equation (104) but that it would also involve the *same* increase in osmotic pressure when added to a solution whose osmotic pressure is π. If such proves to be the case (and we shall see that in many cases, at least, it does), our Modern Theory of Solutions has remained a theory of infinitely dilute solutions, because we have failed to recognize the fact that we have been working with true differential equations, and that in order to obtain the "theory of concentrated solutions" which we have been seeking, the *only thing we needed to do was to integrate our equations.*

In the case of osmotic pressure, for example, if we integrate equation (104), we shall obtain an equation which contains no assumption whatever regarding the concentration. The solution may be infinitely dilute or infinitely concentrated or may have any concentration between these limits. In order to do this we have only to put $V = V_0(1 + \alpha\pi)$, where V_0 is the molecular volume of the pure solvent under the standard pressure P and α is its coefficient of compressibility, and on integration we obtain the Boldingh-van Laar[14] equation for osmotic pressure:

$$\pi + \tfrac{1}{2}\alpha\pi^2 = \left(\frac{-RT}{V_0}\right)\ln(1 - N') \tag{105}$$

---

[14] The history of this equation (105) is very interesting. The differential form as expressed by equation (104) was obtained by van der Waals as early as 1890 (*Z. physik. Chem.*, **5**, 163) but no attempt was made to integrate it, only the case of dilute solutions being discussed, for which case it assumes the form of equation (102) or (100). In 1893 Hondius Boldingh, a student of van der Waals, making use of the thermodynamic potential of Gibbs, derived equation (105) in the following form (Diss., Amsterdam, 1893, p 57):

$$\pi V_0 = -RT \ln(1 - N') + aN'$$

This differs from equation (105) as we have obtained it above, only in the fact that the compressibility of the liquid is neglected and a small correction term aN' is added, a being a quantity which, according to the molecular theory of van der Waals, expresses the mutual influence of the components of the solution upon each other. For "ideal solutions" it is negligible.

Boldingh apparently made no attempt to apply his equation. The same equation was obtained the following year by van Laar (*Loc. cit.*) and in numerous publications

Having come to the conclusion that the integral of equation (104) should represent the osmotic pressure for an "ideal solution," whatever its concentration, we naturally seek for experimental confirmation before adopting it finally.[15] Owing to the great difficulty of making accurate and

---

since then, this investigator has given various derivations of this equation usually by methods involving the thermodynamic potential (cf., however, note 15). In 1897 an osmotic pressure equation in its essential points practically identical with equation (105) was derived by Willard Gibbs (*Nature*, **60**, 461 (1897)) by a method of balanced columns. Finally G. N. Lewis, in a recent paper (THIS JOURNAL, **30**, 675 (1908)), has obtained equation (105) by a derivation involving his "activity" function and based upon the assumption that the "activity" of the solvent is proportional to its mol fraction. Both van Laar (*Proc. Acad. Sci.*, Amsterdam, **9**, 55 (1906)) and Lewis (*Loc. cit.*) have discussed the relation of this equation to the van't Hoff equation and have made comparisons of the values of osmotic pressure given by it with those obtained by Morse and Frazer by direct measurement, in the case of aqueous solutions.

[15] In view of the fact that the van't Hoff equation for osmotic pressure is usually regarded as derivable from the kinetic theory by methods analogous to those used in the kinetic derivation of the perfect gas laws (that is, on the assumption that osmotic pressure is caused by the molecular bombardment of the solute molecules), it may not be without interest to include here a brief kinetic derivation of the differential form of equation (105). For this purpose I shall modify slightly the derivation given by van Laar (*Sechs Vorträge*, p. 20).

Consider two solutions of the same solute in the same solvent, both under the external pressure P and separated from each other by a membrane permeable only to the molecules of the solvent. According to a theorem of Boltzmann, the number of solvent molecules which diffuse per second through a unit surface of the membrane in the two directions is given by the expressions:

(*a*) From the weaker solution to the stronger,

$$n_w = (1 - N'_w)e^{-\frac{\lambda+PV_w}{RT}}. \qquad (107)$$

(*b*) From the stronger solution to the weaker,

$$n_s = (1 - N'_s)e^{-\frac{\lambda+PV_s}{RT}}. \qquad (108)$$

In these equations e is the base of natural logarithms, N'_w and N'_s are the mol fractions of solute in the weaker and the stronger solutions respectively, V is the volume of the solution, R the gas constant, T the absolute temperature and λ a quantity which is a function of the temperature and which depends upon the units of measurement. By adjusting the pressure on the two solutions we can make the number of molecules of solvent which pass in the two directions equal; in other words the two solutions will be in equilibrium as respects the passage of the solvent from one to the other. Under these conditions the right-hand members of the above equations can be placed equal to each other, giving us the equation:

$$(1 - N'_w)e^{-\frac{\lambda+P_wV_w}{RT}} = (1 - N'_s)e^{-\frac{\lambda+P_sV_s}{RT}} \qquad (109)$$

Let us now impose the condition that the "weaker solution" shall be the pure solvent and that the "stronger solution" shall be an infinitely dilute solution in this solvent and shall be under an external pressure P. Under these conditions the above equation assumes the form

$$e^{-\frac{[\lambda+(P+d\pi)V]}{RT}} = (1 - dN')e^{-\frac{(\lambda+PV)}{RT}}. \qquad (110)$$

Dividing through by $e^{-\frac{(\lambda+PV)}{RT}}$ and using the logarithmic instead of the exponential reliable osmotic pressure measurements, it would be an unnecessary waste of time and effort to seek experimental confirmation in this direction, especially as the equation can be tested *just as satisfactorily* by means of its thermodynamic derivatives. Of these we will consider first, the vapor pressure derivative. The thermodynamic relation connecting osmotic pressure and vapor pressure is

nomenclature, we obtain equation (104):

$$d\pi = \left(\frac{-RT}{V}\right) d \ln (1 - N') \qquad (104)$$

After giving a kinetic derivation for equation (105), van Laar follows it with what he terms a "rein thermodynamischer" proof. Such a proof is of course impossible, if by "purely thermodynamic" we are to understand that the equation can be shown to be a necessary consequence of the two laws of thermodynamics and nothing else. In his papers on the subject, van Laar does not distinguish carefully between purely thermodynamic relations and relations which involve additional assumptions. This makes it difficult for the reader, who has not had considerable experience in the use of the thermodynamic potential, to appreciate just what assumptions he is making and what grounds he has for making them. Van Laar also falls into the error of attributing the failure of the modern theory of solutions in the region of concentrated solutions, to an inherent weakness in the osmotic method which he condemns severely, at the same time advocating with great zeal the thermodynamic potential as the *only* quantity which is in a position to completely solve the problem (*Sechs Vorträge*, p. 19). This point of view is absolutely unjustified and is doubtless partially responsible for the fact that the many excellent and valuable features of this investigator's contributions to this problem have not received from the chemical world the consideration which they deserve. Whether we should adopt a system of thermodynamic chemistry based upon the entropy function (as worked out by Horstmann), or upon one of the thermodynamic potentials of Gibbs or Planck, or upon the "fugacity" and "activity" as defined by Lewis or upon the "osmotic pressure" and its related colligative properties, is largely a philosophical question in which the personal equation is an important factor. The "best" system from one point of view is not the "best" from another, and instead of adopting one of these systems and severely condemning the others, we should rather rejoice that the problems of our science are being attacked from these different points of view. All of these systems rest upon the common ground of the first and second laws of thermodynamics and any chemical problem which can be solved in terms of one of them can be solved in terms of all. I cannot therefore agree with van Laar, that the so-called "osmotic" system "läuft auf seinen letzen Beinen" and "nach wenige Jahre wird abgereist sein."

Van Laar also attacks the so-called "gas theory" of solutions, that is, the theory that what we call "osmotic pressure" is a real pressure which exists within an isolated solution due to a molecular bombardment by the solute molecules. On this question, I sympathize largely with van Laar's point of view. His exposition of the difficulties in the way of such a theory is clear and convincing and I shall not, therefore, attempt any further discussion of the question at this time. In this connection, however, it is interesting to recall the views held by Willard Gibbs upon this point. In speaking (*Loc. cit.*) of the osmotic pressure in the case of a solution A, containing a solute, D, he says:

"But we must *not* suppose in any *literal* sense, that this difference of pressure represents the part of the pressure in A which is exerted by the D-molecules, for that would make the total pressure calculable by the law of Boyle and Charles."

$$d\pi = \left(\frac{-v}{V}\right)dp. \qquad (77)$$

Combining this with equation (104) so as to eliminate π we obtain

$$Vdp = RTd\ln N. \qquad (111)$$

If the vapor can be regarded as a perfect gas we can put $v = \frac{RT}{p}$ and obtain

$$d\ln p = d\ln N \qquad (112)$$

which on integration gives

$$p = p_0N \qquad (113)$$

where p_0, the integration constant, is the vapor pressure of the pure solvent. Since the terms solvent and solute are quite arbitrary, we can state therefore in general that the partial vapor pressure of any constituent of an "ideal solution" is proportional to its mol fraction, if the vapor obeys Boyle's law. We have therefore in equation (113) an excellent means of testing our fundamental osmotic equation.

The next question which confronts us is, where are we to look for solutions whose characteristics approach most closely those which we have assumed for our "ideal solution," or in other words where can we find solutions for which we have reason to believe that we know the mol fractions of the constituents in the solution? Our attention is naturally directed towards mixtures of the so-called "normal" liquids of which many examples are to be found among the hydrocarbons of the benzene series and their substitution products. These liquids possess the property of mixing with each other in all proportions, the process of solution being accompanied by little if any heat effects or volume changes, such as would, in general, necessarily occur, if the process of solution were accompanied by chemical reactions such as solvation or changes in the degree of association or dissociation of any of the components. In general the physical properties of these solutions are additive with respect to the constituents. This behavior is, however, just what we should expect in the case of the "ideal solution" which we have assumed. We may therefore expect to find experimental confirmation of our osmotic pressure equation in the case of these solutions. Fortunately data are at hand in the vapor pressure measurements of Zawidski and others. These data show most conclusively that equation (113) expresses the partial vapor pressure for *both* constituents throughout the total concentration range from zero to infinity for some dozen or fifteen different mixtures.[16] Freez-

---

[16] The mixtures which obey this vapor pressure law are as follows:

(1) CO_2—CH_3Cl; (2) C_6H_{14}—C_8H_{18}; (3) $C_2H_4Cl_2$—C_6H_6; (3) $C_2H_4Br_2$—$C_3H_6Br_2$; (2) CH_3OH—C_2H_5OH; (2) $CH_3COOC_2H_5$—$C_2H_5COOC_2H_5$; (2) C_6H_6—$C_6H_5CH_3$; (4) C_6H_6—C_6H_5Cl; (4) C_6H_6—C_6H_5Br; (2) $C_6H_5CH_3$—$C_6H_5C_2H_5$; (4) $C_6H_5CH_3$—C_6H_5Cl; (4) $C_6H_5CH_3$—C_6H_5Br; (2) C_6H_5Cl—C_6H_5Br.

This experimental confirmation of the theory of the ideal or "perfect" solution was pointed out in a recent paper by G. N. Lewis (*Loc. cit.*) who has computed some ing point data furnish additional confirmation of the correctness of our fundamental equation. Van Laar finds, for example, that the "freezing point" curve for solutions of mercury in tin, throughout its entire range (from $t = 232°$ C., $N' = 0$ to $t = -19°$, $N' = 0.9964$), is satisfactorily represented by an equation which rests on the same basis as our fundamental osmotic pressure equation.

This perfect experimental confirmation, combined with the light which is thrown upon the subject by the historical criticism, constitutes a most convincing array of evidence in favor of the adoption of the Theory of the Ideal Solution, as the best provisional *General Theory of Solution.* Before turning to a more detailed consideration of the equations of the Ideal Solution, let us state clearly the general characteristics of such a solution. They are as follows:

I. The number of molecular species present is equal to the number of components.

II. The physical properties of the solution are connected with the physical properties of its components in the pure state by the equation

$$X = xN + x'N' + x''N'' + \qquad (114)$$

in which X is the molecular property in question (*e. g.*, molecular heat capacity, molecular volume, molecular refraction, molecular internal energy, etc.), x (x', x'', etc.) the molecular property of a constituent in the pure state and N (N', N'', etc.) its mol fraction in the solution.

III. The third and most important characteristic is that which describes the thermodynamic relations. The manner of stating this characteristic depends upon what system of thermodynamics one chooses to make use of. I shall therefore state it in three different "languages."

(*a*) *The Gibbs Thermodynamic Potential System.*—According to van Laar the thermodynamic characteristics of the "ideal solution" are expressed by the equation

$$\mu = \mu_0 + RT \ln N \qquad (115)$$

in which μ is the molecular thermodynamic potential of a constituent in the solution, μ_0 the molecular thermodynamic potential of the same constituent in the pure state and N its mol fraction in the solution.

(*b*) *The Fugacity-Activity System of Lewis.*—Lewis uses a system of thermodynamic chemistry based upon two quantities, the "fugacity" ψ, and the "activity" ξ, whose relation to each other is expressed by the equation

$$\psi = \xi RT \qquad (116)$$

and which are connected with the thermodynamic potential by the equation

$$\mu = C + RT \ln \psi \qquad (117)$$

where C is a function of the temperature only. According to Lewis the "perfect solution" is defined by the equation

$$\xi = \xi_0 N \qquad (118)$$

or what amounts to the same thing,

$$\psi = \psi_0 N. \qquad (119)$$

That van Laar's and Lewis' methods of describing the "ideal" or "perfect" solution are identical is made evident by writing equation (119) in the form

$$RT \ln \psi = RT \ln \psi_0 + RT \ln N, \qquad (120)$$

---

tables which exhibit in a very striking manner the excellent agreement of equation (105) with the experimental data, even in the most concentrated solutions.

and combining it with equation (117) when we obtain at once equation (115).

(*c*) *The Colligative Property System or the So-called Osmotic System.*—According to this system, the relation between the colligative properties of the Ideal Solution and its composition is expressed by a set of equations which is composed of the equation

$$d\pi = \left(\frac{-RT}{V}\right) d\ln N \qquad (104)$$

and its thermodynamic derivatives.[17]

Having established fundamental equations for the Ideal Solution, let us now derive a set of equations for such a solution similar to our present equations for dilute solutions, but free from any assumptions as to the concentration of the solution. In deriving such a set of equations we could start either with our osmotic pressure equation (104) or the vapor pressure derivative (112). In either case we should obtain the same set of equations. There is not much reason for choosing one of these equations rather than the other as a starting point. Each possesses certain advantages for this purpose. In the following derivations, however, I shall start with the osmotic pressure equation (104) in each case. This procedure will allow of direct comparison with our corresponding derivations for dilute solutions and it moreover avoids the necessity of using the gaseous phase in the derivation of a relation which is independent of the properties of the vapor. The procedure for obtaining our set of equations is very simple. In each instance, it consists simply in combining equation (104) with the proper purely thermodynamic relation and then integrating the result. The purely thermodynamic relations have all been obtained by the author in the previous publication[3] to which the reader is referred for their derivation. For convenience in reference these equations will be designated by the same numbers as in the preceding publication. All numbers below 100 refer to the previous paper.

3. Vapor Pressure.

We have already derived this equation for which the integrated form is

$$p = p_0 N \qquad (113)$$

where p is the partial vapor pressure of any molecular species from an ideal solution in which its mol fraction is N, and p_0 is its vapor pressure in the pure liquid state at the same temperature. For a single non-volatile solute whose mol fraction is N' this can also be written in the form

$$\frac{\Delta p}{p_0} = N' = \frac{n'}{(n + n')}. \qquad (121)$$

If in a mixture of say two liquids, polymerization of one or both constituents, or chemical combination between them occurs, we can obviously make use of equation (113) to determine the exact nature and extent of these processes if we know the necessary partial vapor pressure data. Derivatives of equation (113) for special cases of association and of chemical combination have been applied recently with considerable success by Ikeda[18] and by Dolezalek[19] to the elucidation of the chemical condition of several pure liquids and of their mixtures. The accumulation of accurate and reliable vapor pressure data is of the highest importance to a clearer and more complete knowledge of the nature of solutions. For reasons which I have stated elsewhere,[21] the vapor pressure equation is the relation best adapted to serve as a basis for the experimental attack on the problem of concentrated solutions.

---

[17] Regarding the general characteristics of the Ideal Solution as stated above, it should be noted that although *in general* the *absence* of heat effects or volume changes on mixing two liquids may be taken as evidence for the absence of accompanying chemical reactions, the reverse is not necessarily the case. Heat effects and volume changes *may* and doubtless do occur in the absence of any chemical reaction, although in such a case the heat effect will in the majority of cases be of quite a different order of magnitude from that which is caused by a chemical reaction.

4. The Freezing Point Equation.

If we combine the purely thermodynamic equation

$$d\pi = \left(\frac{-L_F}{V}\right)\frac{dT_F}{T_F} \tag{82}$$

with our fundamental equation

$$d\pi = \left(\frac{-RT}{V}\right) d\ln N \tag{104}$$

so as to eliminate π, we obtain the desired equation[20]

$$dT_F = \left(\frac{RT_F^2}{L_F}\right)\left(\frac{dN}{N}\right) = \left(\frac{-RT_F^2}{L_F}\right)\left(\frac{dN'}{N}\right). \tag{122}$$

For *very dilute* solutions, we *can* of course substitute the freezing point lowering Δt_F in place of $-dT_F$ and $\frac{n'}{n}$ in place of $\frac{dN'}{N}$ and obtain the familiar law of Raoult-van't Hoff for freezing point lowering in dilute solution:

$$T_0 - T_F = \Delta t_F = \left(\frac{RT_0^2}{L_F}\right)\left(\frac{n'}{n}\right) \tag{124}$$

It is preferable, however, to integrate our differential equation and thus obtain a general equation for an ideal solution of any concentration. Before doing this we will substitute in equation (122)

$$T_0 - \Delta t_F = T_F,\ 1 - N' = N \text{ and } -d(\Delta t_F) = dT_F$$

where Δt_F is the freezing point lowering in centigrade degrees and T_0 is the freezing point of the pure solvent on the absolute scale. This gives us

$$\frac{dN'}{d(\Delta t_F)} = \frac{L_F(1-N')}{R(T_0 - \Delta t_F)^2}. \tag{125}$$

In order to integrate, we must first express L_F as a function of Δt_F which is done by the following purely thermodynamic equation:

$$L_F = L_{F_0} - \Delta Cp_0 \Delta t_F - {}^1/_2\alpha(\Delta t_F)^2 - {}^1/_3\beta(\Delta t_F)^3 - \ldots \tag{85}$$

---

[18] Ikeda, *J. Coll. Sci. Imp. Univ. Tokyo*, 25, Art. 10 (1908).

[19] Dolezalek, *Z. physik. Chem.*, 64, 730 (1908); see also Möller, *Ibid.*, 69, 449 (1909).

[20] This equation was obtained by Boldingh (*Loc. cit.*, p. 61) in the following form:

$$\left(\frac{L_F}{R}\right)\left(\frac{dT_F}{T_F^2}\right) = \left[\frac{1}{(1-N')} + 2aN'\right] dN' \tag{123}$$

where a has the meaning explained in note (14). Boldingh integrated his equation under the assumption that L_F is independent of T.

In this equation L_{F_0} is the molecular heat of fusion of the pure solvent at its freezing point T_0, ΔC_{P_0} is the attendant decrease in the heat capacity of the system and α, β, etc., are constants expressing the dependence of ΔC_P upon the temperature. Combining (85) with (125) we obtain finally (neglecting β):

$$\frac{dN'}{d(\Delta t_F)} = \frac{[L_{F_0} - \Delta C_{P_0} - {}^1/_2\alpha(\Delta t_F)^2](1 - N')}{R(T_0 - \Delta t_F)^2} \qquad (126)$$

This equation can now be integrated. A convenient way to do this is to integrate into a power series in the desired variable by applying McLaurin's theorem directly to the differential equation, carrying the series only so far as the accuracy of the experimental data warrant for the particular case under consideration. For example, in the case of water solutions if Δt_F be known to 0.001°, then for values of Δt_F which do not exceed 7°, the terms containing α, β, etc., are negligible and the application of McLaurin's theorem gives us the equations[21]

$$N' = \frac{L_{F_0}}{RT_0^2}\left[\Delta t_F - {}^1/_2\left(\frac{L_{F_0}}{RT_0^2} + \frac{\Delta C_{P_0}}{L_{F_0}} - \frac{2}{T_0}\right)(\Delta t_F)^2\right] \qquad (127)$$

and

$$\Delta t_F = \frac{RT_0^2}{L_{F_0}}\left[N' + {}^1/_2\left(1 + \frac{RT_0^2\Delta C_{P_0}}{L_{F_0}} - \frac{2RT_0}{L_{F_0}}\right)N'^2\right], \qquad (128)$$

the remaining terms in the expansion not being significant.

If we desire to follow a freezing point curve through a considerable range of temperature, the general integral of equation (126) is more advantageous. The general integral is

$$R \ln (1 - N') = (\Delta C_{P_0} + \alpha T_0) \ln \frac{(T_0 - \Delta t_F)}{T_0} - \frac{[L_{F_0} - (\Delta C_{P_0} + \alpha T_0)\Delta t_F + {}^1/_2\alpha \Delta t_F{}^2]}{(T_0 - \Delta t_F)} + \frac{L_{F_0}}{T_0}. \qquad (129)$$

Equations of this general character have been derived by several observers[22] and the corresponding theoretical curves have been compared with the experimental curves for a number of systems with good agreement. In these comparisons, however, the constants of the theoretical equation have been evaluated from the freezing point data themselves, so that the agreement loses a good deal of its significance.

5. The Boiling Point Equation.

By combining the purely thermodynamic equation

$$d\pi = \left(\frac{L_v}{V}\right)\left(\frac{dT_B}{T_B}\right) \qquad (90)$$

---

[21] The application of equation (127) to the data for aqueous solutions and the interpretation of the results obtained have been discussed by the author in a previous paper (*Technology Quarterly*, 21, 370 (1908)). This application was made on the assumption that the molecular weight of liquid water is 18. Although the results obtained on this assumption were fairly satisfactory up to a concentration of 1 molal, it is clear that a complete study of the behavior of aqueous solutions from the standpoint of the laws of the Ideal Solution must take into account the degree of association of the solvent. Further investigations along this line are now in progress in this laboratory.

[22] *e. g.*, van Laar (*Versl. K. Akad. van Wet.*, Amsterdam, 1903 and 1904; several papers) Roozeboom (*"Die Heterogene Gleichgewicht,"* 2, 267 *et. seq.*), and Yamamota (*J. Coll. Sci. Imp. Univ. Tokyo*, 25, Art. 11 (1908)).

with equation (104) so as to eliminate π we obtain the desired equation

$$dT_B = \left(\frac{RT_B^2}{L_v}\right)\left(\frac{dN'}{N}\right). \tag{130}$$

which for very dilute solutions takes the familiar form

$$T_B - T_{Bo} = \Delta t_B = \left(\frac{RT_{Bo}^2}{L_v}\right)\left(\frac{n'}{n}\right). \tag{131}$$

In order to integrate the differential equation (130) we have only to express L_v as a function of the temperature. The First Law of Thermodynamics gives us the rigorous equation

$$\frac{dL_v}{dT} = c_p - C_P + \frac{L_v}{T} - \left(\frac{L_v}{v}\right)\left(\frac{\partial v}{\partial T}\right)_p \tag{132}$$

by means of which we can calculate the temperature coefficient of L_v. If the vapor behaves as a perfect gas this equation becomes

$$\frac{dL_v}{dT} = \Delta C_P \tag{133}$$

and the methods of integration of equation (130) become perfectly analogous in every respect to those followed in the case of the freezing point equation in the preceding section. It is not necessary therefore to discuss them in detail. The final equations have the same form as the corresponding ones for the freezing point lowering.

6. Chemical Equilibrium.

Two examples will be sufficient to illustrate the method of derivation of the laws which regulate chemical equilibrium in the ideal solution. Let the equilibrium be expressed by the equation:

$$a\mathrm{A} + b\mathrm{B} + \ldots \rightleftarrows m\mathrm{M} + n\mathrm{N} + \ldots \tag{134}$$

(*a*) *The Effect of Concentration.*—The purely thermodynamic equation for the effect of concentration upon chemical equilibrium in a liquid phase at constant temperature and pressure is

$$-aV_{\mathrm{A}}d\pi_{\mathrm{A}} - bV_{\mathrm{B}}d\pi_{\mathrm{B}} - \ldots + mV_{\mathrm{M}}d\pi_{\mathrm{M}} + nV_{\mathrm{N}}d\pi_{\mathrm{N}} + \ldots = 0. \tag{30a}$$

According to equation (104) the osmotic pressure for each substance taking part in the equilibrium is

$$V_{\mathrm{X}}d\pi_{\mathrm{X}} = -RTd\ln N_{\mathrm{X}}. \tag{135}$$

Combining these two equations we obtain the relation

$$\frac{N_{\mathrm{A}}^a \cdot N_{\mathrm{B}}^b \cdots}{N_{\mathrm{N}}^n \cdot N_{\mathrm{M}}^m \cdots} = K_N \tag{136}$$

where K_N is a constant. This expression differs from the Guldberg-Waage Law only in the substitution of the mol fraction N, in place of the volume concentration C. Equation (136) was obtained by Planck[23] as early as 1887, and the reasons for adopting it in place of the Guldberg-Waage form and for expressing the composition of solutions in terms of mol fractions instead of mols per liter were clearly stated by him at the same time.

(*b*) *The Effect of Temperature.*—The purely thermodynamic relation is

$$-aV_{\mathrm{A}}d\pi_{\mathrm{A}} - bV_{\mathrm{B}}d\pi_{\mathrm{B}} - \ldots + mV_{\mathrm{M}}d\pi_{\mathrm{M}} + nV_{\mathrm{N}}d\pi_{\mathrm{N}} + \ldots = \frac{Q_\pi dT}{T}. \tag{38a}$$

---

[23] Planck, *Wied. Ann.*, 32, 489 (1887).

Combining this with equations (136) and (135) and introducing the First Law of Thermodynamics we obtain the equation

$$\frac{d\ln K_N}{dT} = \frac{U}{RT^2} \quad . \qquad (137)$$

which is identical with the van't Hoff Law, with the substitution of K_N in place of the Guldberg-Waage constant K_C. In general it may be stated that the laws for chemical equilibrium in an ideal solution may be obtained from our present dilute solution laws by substituting mol fractions in place of volume concentrations. This applies also to heterogeneous equilibrium. The Solubility Product Law, for example, for a saturated solution of the solute BC which dissociates into B and C becomes[24]

$$N_B \cdot N_C = const. = K_S. \qquad (138)$$

7. Concluding Discussion.

Lest any one from the perusal of the foregoing pages should gain the impression that the problem of a satisfactory general theory of solutions may be regarded as completely solved, it will be well to examine for a moment, in a general way, the characteristics of the Theory of the Ideal Solution with respect to its advantages and disadvantages when regarded as the basis for a general theory of solutions. When compared with the Theory of Dilute Solutions we must acknowledge that it constitutes a distinct and decided step forward. One requirement of a satisfactory general theory of solutions is that it shall represent the facts throughout the whole range of concentrations for some type of solution, at least. This requirement is fulfilled by the Theory of the Ideal Solution and we may feel considerable certainty that any deviation from the requirements of this theory, in a given case, is due to physical or chemical causes and capable of a physical or chemical explanation and is not simply the result of attempting to apply a set of incomplete laws which do not and could not be expected to hold for any kind of a concentrated solution no matter how simple its character.

The success of the Theory of the Ideal Solution as an instrument for throwing light upon the processes occurring in solutions has already been demonstrated in several instances. In the case of several solutions which apparently exhibit a behavior contrary to the requirements of the Theory, Dolezalek[19] has shown that perfect agreement between theory and experiment exist if the assumption be made that a simple compound is formed between the two constituents or that one of them is partially associated. In the case of acetone and chloroform for example, the assumption of a single compound, $CHCl_3(CH_3)_2CO$, and the introduction of the corresponding equilibrium constant into the equations sufficed to produce complete agreement between theory and experiment. It is true that the value of the constant was computed from the vapor pressure data themselves, but in a recent paper[19] Möller has shown that the values of such constants may be obtained independently of the vapor pressure data of the solution under consideration and that they therefore possess the physical significance ascribed to them and are not simply empirical constants of an interpolation formula.

---

[24] This is obtained by combining equations (51) and (104). It does not involve the Mass Action Law [*i. e.*, equation (136)], which is usually assumed as the basis for the derivation of the Solubility Product Law. This point, which was brought out in the previous paper, has been overlooked in all of the textbooks of physical chemistry, although it was explained clearly by Planck as early as 1887 (*Loc. cit.*).

In all the cases studied by Dolezalek he found that agreement between experiment and theory is produced if the assumption be made that what appears to be a deviation from the theory is simply due to the fact that the numbers assumed as the mol fractions of the two constituents in the solution are incorrect and that when the proper mol fractions are used, the apparent discrepancy disappears. If we were justified in assuming that *all* solutions are really ideal solutions and that what appear to be exceptions are merely due to our inadequate knowledge of the number and kind of the various molecular species present and their respective mol fractions, then the Theory of the Ideal Solution would constitute a general theory including all solutions and all concentrations and would enable us to ascertain just what occurs chemically, when the solution is formed out of its constituents. Unfortunately such is not the case, for it can be easily shown mathematically that if certain liquids form an ideal solution with one another they must be miscible in all proportions. The solutions in a system composed of two or more liquid phases in equilibrium with one another cannot therefore be governed to the laws of the Ideal Solution. Moreover, these exceptions are not merely apparent but are real and cannot be explained on the grounds of association, dissociation or chemical combination. The explanation must be looked for in a radical difference in the physical nature of the medium.

To illustrate by an extreme case, let us consider a system composed of a solution of benzene in mercury and a solution of mercury in benzene, both solutions in equilibrium with each other. The vapor pressure of benzene from the mercury layer is equal to its vapor pressure from the benzene layer and yet the mol fraction of benzene in the mercury layer is probably so small that we could not detect it by any analytical means, while in the benzene layer it is equal to 1, within the limits of our ability to measure it. The equality of the vapor pressure from the two layers can only be due, therefore, to the fact that the nature of the medium between the molecules of mercury is such that the benzene molecules can penetrate it only with the greatest difficulty. This effect of the physical nature of the medium is therefore one which must be taken account of in all applications of the Theory of the Ideal Solution. In order that the laws of the Ideal Solution shall apply, the nature of the medium or the field of force in which the molecules find themselves in the solution must not be *very* different from that of the pure liquid itself. Although this restricts somewhat the sphere of usefulness of the theory, there still remain a large number of cases where it should prove of the greatest value in the elucidation of the chemical nature of solutions. Even in cases where the theory cannot be extended over all concentrations because of a consequent radical change in the physical nature of the medium, we may still hope to obtain valuable results with its aid in solutions of moderate concentrations. At all events, I believe that the Theory of the Ideal Solution is the one which should be adopted as the basis for reference, classification and interpretation of the experimental data on solutions in place of our present Theory of the Infinitely Dilute Solution which is only a special, though very important, case of the former theory.

URBANA, ILLINOIS, Feb. 1, 1910.

[FROM THE PHYSIOLOGICAL LABORATORY OF THE CORNELL UNIVERSITY MEDICAL COLLEGE, NEW YORK.]

THE FATE OF THE AMINO ACIDS IN THE ORGANISM.[1]

BY GRAHAM LUSK.

Received February 15, 1910.

Only a few years ago the chemical composition of protein was absolutely unknown. In many quarters the accepted idea was that voiced by Bidder and Schmidt in 1852, namely that all the nitrogen of protein together with enough carbon, hydrogen and oxygen to form urea were split from combination in protein, while the remainder was burned to carbon dioxide and water, thereby yielding heat to the organism. Voit believed that this non-nitrogenous remainder yielded carbohydrate, as was particularly evident in diabetes and also fat. Indeed the conception of the structure of the protein molecule was quite like that which Levene has so splendidly shown to be characteristic of nucleic acid, *i. e.*, a molecule made up of carbohydrate united with phosphoric acid on the one side, and with nitrogen-containing purine and pyramidine bases on the other. The modern conception of the protein molecule as a huge complex of amino acids riveted together dates from the work of Emil Fischer. Fischer has strung together eighteen of these amino acids in an artificial compound, a peptide called *l*-leucyl-triglycyl-*l*-leucyl-triglycyl-*l*-leucyl-octoglycyl-glycine, a body similar to peptone. Already Fischer has prepared over a hundred such artificial polypeptides.

Proteins differ, as they contain different amino acids. Fischer, in an address given in 1907, expressed the opinion that the proteins then known were merely mixtures of substances, and were not pure individuals. He would not attribute all the great multitude of amino acids found on hydrolysis to a single chemical unit. Osborne, however, takes a different view and believes that his beautifully prepared crystals of plant protein "show a constancy of properties and ultimate composition between uccessive fractional precipitations which give no reason for believing the substance to be a mixture of two or more individuals." He adds: "Of twenty-three seed proteins which have been hydrolyzed all have yielded leucine, proline, phenylalanine, aspartic acid, glutamic acid, tyrosine histidine, arginine and ammonia. Glycocoll, lysine and tryptophane are the only amino acids which have been proved lacking in any of these proteins." Other amino acids not mentioned above, but frequently revealed, are alanine, valine, serine, cystine, proline, and oxyproline. The chains of amino acids forming this complex must be of immense size to comprise the many and varied elements set forth above. Osborne calculates the molecular weight of protein at 15000 or some higher multiple of this.

---

[1] A paper read before the New York Section of the Chemical Society, February 11, 1910.

In general, the same constituent amino acids are present in both plant and animal protein. There is no fundamental dividing line. Hence the animal may eat the plant protein, break it by digestion into its constituent amino acids, and then reconstruct these into proteins of another order, those characteristic of animal tissues. Osborne[1] calls attention to the fact that the food proteins which are found in flour are those which are prepared within the endosperm of wheat for the nutrition of the wheat embryo. In the commercial process of milling these embryos are separated and discarded. Bread therefore contains the same nutrient proteins as those provided for the embryo of the wheat.

Osborne finds that seeds which are botanically closely related contain similar food proteins, although those of the leguminous seeds differ greatly from those of the cereals. Hence the developing plant embryo is supplied with a definite food which for each individual of the same species is the same, but for those of different species is different.

It is the same thing in the animal. The genitalia of the fasting salmon grow at the expense of the muscle tissue, as was shown by Miescher, and Jägerroos has adduced evidence which shows that the young of a pregnant dog may be largely nourished at the expense of the protein of the maternal organism. And at all times the unborn animal is furnished with nutrient material of the mother's blood.

Rubner has classified food protein into three divisions representing three varieties of physiological use. The first is the "wear and tear" quota or the amount required to balance the normal waste of tissue protein. The second in the "growth quota," or that necessary for the growth of the body. The third is the "dynamic quota" or that which is used merely to maintain the energy of the cells and whose function may be replaced by carbohydrate or by fat.

In adult life the fundamental use for food protein is to prevent the loss of body protein. If the organism be given fat or carbohydrate alone there will be a constant loss of body protein, the "wear and tear" quota of Rubner. This will continue unless new protein or amino acids are given to replace that lost to the body. Here only the proper array of amino acids will furnish new materials for replacement of the old. For example, if tryptophane be absent from the food, no replacement is possible.

In the growing and even in the adult animal there are conditions in which protein is added to the body. That portion of the food protein retained for growth is the "growth quota." This growth is accomplished at the expense of amino acids formed from ingested protein. Very often protein is taken in excess of that required for the replacement of the "wear and tear" quota and in such excess that the optimum protein content of the cells is reached and no new deposit from the "growth quota" is possible. What then becomes of the excess? Instead of such protein being retained in the organism, it is broken up, its nitrogen is found in the urine as urea, and its deaminized remainder furnishes fuel for the organism. This is the "dynamic quota."

---

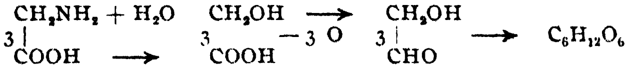
[1] Osborne "The Vegetable Proteins," 1909.

Modern knowledge indicates that the amino-acid nitrogen not used for growth is split off from its combination in the form of ammonia and this ammonia, uniting with carbon dioxide, is carried as ammonium carbonate to the liver and there synthesized to urea. Whenever single amino acids are ingested their nitrogen content appears in the form of urea in the urine. Convincing and recent evidence of this theory is that afforded by Otto Cohnheim, who filled the intestines of fish with albumoses and on suspending the intestines in saline (Ringer's) solution witnessed a large evolution of ammonia. Amino acids similarly treated gave the same results. Very striking also are the experiments of Weinland on the larvae of the blow-fly, which derive their nutriment from meat. These larvae may devour an amount of meat equal to sixty per cent. of their own weight within a space of two days. A large part of this meat protein they convert into fat, the nitrogen content being eliminated as ammonia. When this well-established biological principle of the origin of fat from protein is considered in connection with the fact that in diabetes sugar may arise from protein to the extent of nearly sixty per cent., it becomes evident that there may be a condition of nutrition in which protein is used neither for repair nor for growth, but simply to be deaminized and subsequently to act like fat or carbohydrate as nutritive materials for the organism. This represents the "dynamic quota" of Rubner, the portion of food protein used for energy alone and which may be equally well furnished in the form of fat or carbohydrate.

How, then, does such a conversion of amino acids into carbohydrates and fat occur? To have a complete knowledge concerning this, one must know the fate of each individual amino acid ingested into the organism.

Dr. Ringer and I have recently taken up the subject of sugar production from amino acids. We have given various such acids to diabetic dogs. We have noticed that the nitrogen elimination in the urine increased in amounts which corresponded to that ingested and that this increase was all due to urea nitrogen. We have given glycocoll, alanine, aspartic acid, glutamic acid, containing respectively two, three, four and five carbon atoms. It was found that all the glycocoll and all the alanine were converted into glucose, whereas three of the carbon atoms contained in aspartic and glutamic acids were so converted.

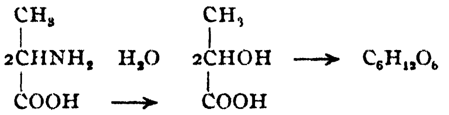
The process of the deamination of these substances is believed to be one of hydrolysis. After this fashion glycolic acid would be produced from glycocoll. If this were converted into glycolic aldehyde, then three molecules of the latter would form one of sugar, and indeed the subcutaneous injection of glycolic aldehyde into a rabbit leads to the elimination of sugar in the urine.[1] These reactions would thus be written:



$$\begin{array}{llll} \mathrm{CH_2NH_2 + H_2O} & \mathrm{CH_2OH} \longrightarrow & \mathrm{CH_2OH} & \\ 3\,| & 3 \qquad -3\,\mathrm{O} & 3\,| & \longrightarrow \mathrm{C_6H_{12}O_6} \\ \mathrm{COOH} \longrightarrow & \mathrm{COOH} & \mathrm{CHO} & \end{array}$$

Glycocoll. Glycolic acid. Glycolaldehyde. Glucose.

Next, in the case of the amino-acid alanine, we found that it also may be completely converted into dextrose. The reaction may involve the production of lactic acid from alanine by hydrolysis and the synthesis of two molecules of lactic acid into dextrose. This reaction would read:



$$\begin{array}{llll} \mathrm{CH_3} & & \mathrm{CH_3} & \\ | & & | & \\ 2\mathrm{CHNH_2} & \mathrm{H_2O} & 2\mathrm{CHOH} & \longrightarrow \mathrm{C_6H_{12}O_6} \\ | & & | & \\ \mathrm{COOH} & \longrightarrow & \mathrm{COOH} & \end{array}$$

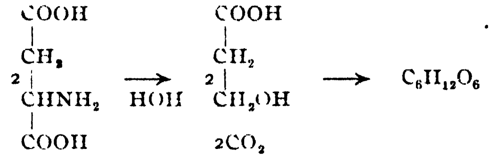
Alanine. Lactic acid. Glucose.

Several years ago Arthur Mandel and I gave a diabetic dog subcutaneous injections of *d*-lactic acid and saw that it was completely converted into glucose. Lactic acid therefore could circulate throughout the body's tissues without being oxidized and when it reached the liver be synthesized to glucose and be eliminated through the kidney of the diabetic. This introduces the question whether lactic acid can ever be directly oxidized by the organism or whether it must not first be converted into glucose. This fate of alanine is also suggested by the work of Neuberg, who gave alanine to a normal rabbit and found glycogen stored in the liver and lactic acid eliminated in the urine. The idea that lactic acid of itself cannot be oxidized accords with the work of Neubauer,[2] which indicates that the deamination of the side chain of tyrosine is not accomplished by simple hydrolysis but by a simultaneous oxidation process, with the production of a ketone instead of an alcohol. The ketone is combustible in the organism, the alcohol not. This reaction will be taken up in connection with the fate of tyrosine. According to this view, pyroracemic acid, $CH_3COCOOH$, would have to be the product of the oxidative deamination of alanine, if the latter were to be directly oxidized. Since the deaminized acid is protected from oxidation, it appears to be probable that lactic acid is the primary product involved in this case. Hence the normal fate of alanine occurs by way of hydrolysis to lactic acid which the organism cannot oxidize except indirectly by synthesis to glucose.

[1] Mayer, *Z. physiologische Chemie, Bd.*, 38, 151 (1903).

[2] Neubauer, "Ueber die Abbau der Aminosäuren," Habilitationsschrift, 1908.

When Dr. Ringer and I gave aspartic acid to a dog with phlorhidzin glucosuria we observed an elimination of extra sugar in the urine equal to the conversion of three out of its four carbon atoms into glucose. The probable course of metabolism in this instance is as follows:

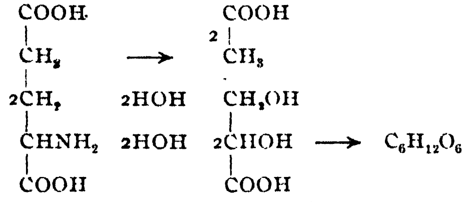


$$2\begin{array}{l}\mathrm{COOH}\\ |\\ \mathrm{CH_2}\\ |\\ \mathrm{CHNH_2}\\ |\\ \mathrm{COOH}\end{array}\xrightarrow{\mathrm{HOH}}2\begin{array}{l}\mathrm{COOH}\\ |\\ \mathrm{CH_2}\\ |\\ \mathrm{CH_2OH}\\ \\ 2\mathrm{CO_2}\end{array}\longrightarrow \mathrm{C_6H_{12}O_6}$$

Aspartic acid β-Lactic acid. Glucose.

It is interesting in this connection to note that Höckendorf[1] has observed an increase in the sugar elimination following administration of propyl alcohol to a phlorhidzinized dog, and although some of his results must be accepted with a certain reserve, Dr. Ringer and I have been able to confirm the above observation. Hockendorf's method of single injections of phlorhidzin each day instead of at eight hour intervals calls for severe criticism.[2]

Concerning the fate of glutamic acid where again three atoms of the molecule go over into glucose, the following argument is proposed. When fatty acids are oxidized in the body Knopp has shown that there is a primary oxidation at the β-carbon atom with a cleavage of acetic acid from the chain, which latter is then readily destroyed. If such a method were employed in the metabolism of glutamic acid, acetic acid and glyceric acid would result, the latter of which might be converted into glucose. The reaction would be as follows:



$$2\begin{array}{l}\mathrm{COOH}\\ |\\ \mathrm{CH_2}\\ |\\ \mathrm{CH_2}\\ |\\ \mathrm{CHNH_2}\\ |\\ \mathrm{COOH}\end{array}\xrightarrow{2\mathrm{HOH}\ \ 2\mathrm{HOH}}\begin{array}{l}\mathrm{COOH}\\ 2\,|\\ \mathrm{CH_3}\\ \\ \mathrm{CH_2OH}\\ |\\ 2\mathrm{CHOH}\\ |\\ \mathrm{COOH}\end{array}\longrightarrow \mathrm{C_6H_{12}O_6}$$

Glutamic acid. Glyceric acid. Glucose.

Ringer and I, in confirmation of this theory, have given a diabetic dog sodium acetate without increasing the quantity of glucose in the urine, whereas the administration of glyceric acid caused a large increase in the output of glucose.

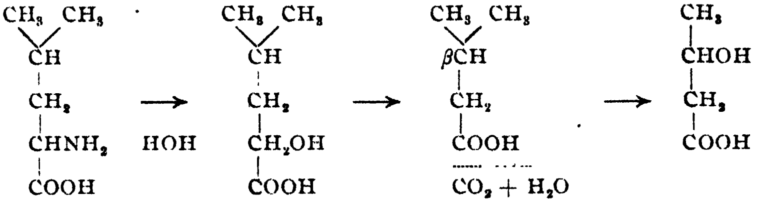
Since serine, on deamination, would be converted into glyceric acid, it is apparent that this amino acid also is probably convertible into glucose.

---

[1] Höckendorf, *Biochemische Zeitschrift* (1909), *Bd.*, 23, 295.

[2] See Stiles and Lusk, *Am. J. Physiol.*, 10, 67 (1903).

Halsey[1] obtained conflicting results after giving leucine to phlorhidzinized dogs, and doubts the conversion of leucine into glucose. Baer and Blum[2] have found an increased output of β-hydroxybutyric acid in the urine after giving leucine to a diabetic man and the following transformation has been attributed to it:

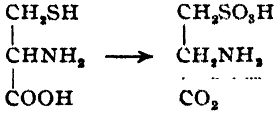


Leucine. Hydroxyisobutyl acetic acid. Isovaleric acid. β-Hydroxybutyric acid.

The fate of *valine* is unknown. Whether it is converted into glucose or not is yet to be determined. Baer and Blum report that it is not convertible into β-hydroxybutyric acid.

Of lysine, a diaminocaproic acid, one can only speculate that it may yield glucose, perhaps to the extent of half of its molecule. Less probable appears the prospect of obtaining glucose from arginine. The metabolism of pyrrole derivatives, such as proline, of indole, of derivatives like tryptophane, or of histidine with its imidazole ring, is too obscurely known to make any prediction.

Cystine, with its sulphur content, is the mother substance of the taurine of the bile and apparently is deaminized less readily than other amino acids. Its conversion into taurine is given by Friedmann as follows:



$$\begin{array}{c} CH_2SH \\ | \\ CHNH_2 \\ | \\ COOH \end{array} \longrightarrow \begin{array}{c} CH_2SO_3H \\ | \\ CH_2NH_2 \\ \text{-----} \\ CO_2 \end{array}$$

Cystine. Taurine.

Any further intermediary products of cystine metabolism are unknown.

Finally there remain tyrosine and phenylalanine to be considered. The fate of these acids has been in part revealed by the work of Neubauer and Falta[3] and of Neubauer[4] alone. Under ordinary circumstances these acids are oxidized in the body with the complete destruction of the benzene ring. The breaking up of the ring in these substances is dependent upon the presence of the amino radicle in the *alpha*-position on the side chain. In a disease called alkaptonuria these substances only reach the homogentisic acid stage and are then eliminated in the urine. Homogentisic acid, which is destroyed by a normal individual, cannot be oxidized by the alkaptonuric patient any more than glucose can be destroyed by the diabetic. The general transformation is as follows:

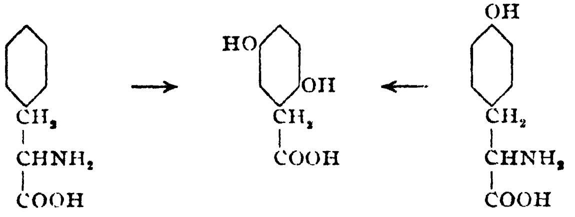
---

[1] Halsey, *Am. J. Physiol.*, 10, 229 (1904).

[2] Baer and Blum, *Arch. exper. Path. Pharm.*, 4, 89 (1906).

[3] Neubauer and Falta, *Z. physiol. Chem.*, 42, 81 (1904).

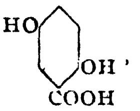
[4] Neubauer, *Loc. cit.*



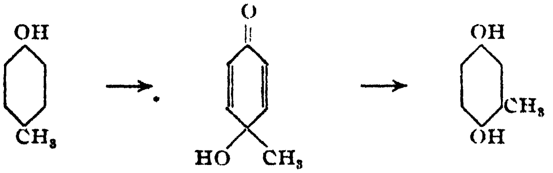
Phenylalanine. Homogentisic acid. Tyrosine.

Neubauer states that the hydroxyl group on the benzene ring must be in the para position, or the transformation into homogentisic acid is impossible.

Neubauer finds that the alkaptonuric has lost the power to break the benzene ring. He confirms this by showing that gentisic acid, is oxidized by the normal individual but is not attacked by a person with alkaptonuria. He is astonished at the discovery that the alcohol, hydroxyphenyllactic acid, which is formed from tyrosine by hydrolytic deamination, is not oxidized into homogentisic acid by the organism, whereas the ketone, oxyphenylpyroracemic acid is so converted. From this he reaches the important conclusion that in this case there is oxidative deamination and not deamination by simple hydrolysis.

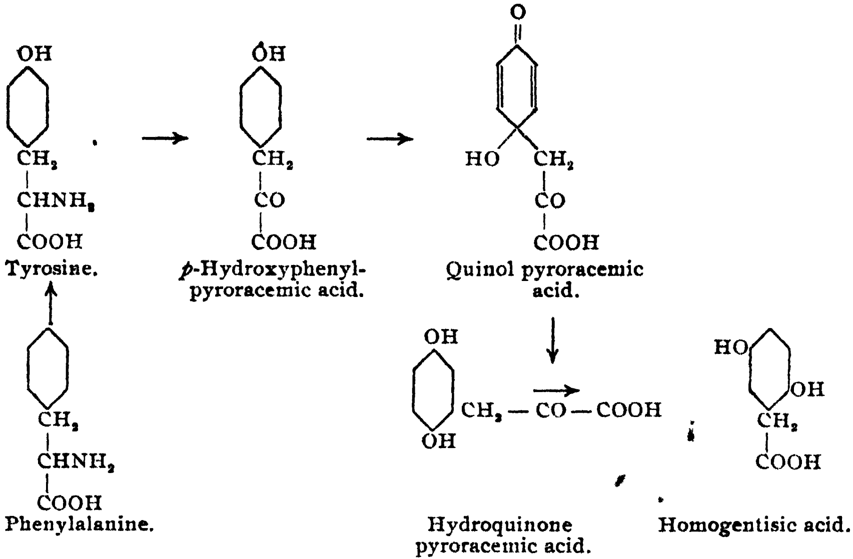


Erich Meyer was the first to call attention to the possibility of the conversion of tyrosine into homogentisic acid through a quinol stage. This is illustrated by the laboratory oxidation of paracresol with per sulphuric acid.



p-Cresol. *p*-Toluquinone. Toluhydroquinone.

The formation of homogentisic acid from tyrosine presents so close an analogy to the above that Neubauer assumes a similar process. The complete reaction would then be:

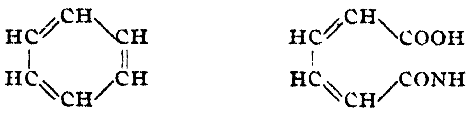


Tyrosine. *p*-Hydroxyphenylpyroracemic acid. Quinol pyroracemic acid.

Phenylalanine. Hydroquinone pyroracemic acid. Homogentisic acid.

It may be of interest to state in passing that this work on the fate of tyrosine was accomplished by a physician in one of the great medical clinics of Germany where opportunities for such work are liberally afforded.

Regarding the further fate of homogentisic acid, the observation of Jaffé[1] that after feeding benzene to animals, muconic acid may be detected in the urine, is of importance. This indicates that the oxidation of the benzene nucleus takes place as follows:



Benzene. Muconic acid.

Should this be the method of breaking the ring, then the straight chain of the dibasic hydroxy acid which would be produced from homogentisic acid would be readily oxidized. It is said that tyrosine, when ingested in diabetes, increases the amount of acetone bodies in the urine (Baer and Blum).

Dr. Ringer and I have investigated the subject of the possibility of its yielding glucose in the body and so far our results have been negative. Since inosite, a hexahydroxybenzene, is completely destroyed by the diabetic, negative results from tyrosine were to have been expected.

In this discussion of the fate of the amino acids in the organism it has been brought out that in their final cleavage products are found either sugar or fatty acid. It is these substances which are the energy givers to the cells. They act as fuel for the machinery of life. In their preparation from protein there are many cleavages, and perhaps oxidations which yield free heat to the organism without ever giving vital energy to the cells. In consequence of this, protein ingestion results in a considerable increase in the amount of heat liberated within the body. This is the *specific dynamic action* of protein in increasing heat production in accordance with the doctrines of Rubner.

---

[1] Jaffé, *Z. physiol. Chem.*, 72, 58 (1909).

As regards the sugar production from meat, for example, one may now in a crude way estimate its source. I have found that in diabetes fifty-eight parts of glucose may arise from one hundred parts of meat protein. Osborne's[1] latest results of the analysis of ox muscle include the following figures:

	Parts in 100
Glycocoll	2.06
Alanine	3.72
Aspartic acid	4.51
Glutamic acid	15.49

In a paper read in Boston recently, Osborne indicated that owing to the inaccuracy of the Fischer ester method, the figures for alanine and aspartic acid may easily be twice the amounts stated above. Likewise, the work of Parker and Lusk indicates that four grams of glycocoll may arise in the metabolism of flesh within the body of a rabbit, and similar results have been obtained in man. If we substitute these increased quantities for the analytical results obtained by Osborne and then calculate the sugar production from the various acids as obtained in the laboratory, we arrive at the following results:

	Parts in 100 of ox muscle (estimated).	Glucose production (calculated)
Glycocoll	4.0	3.2
Alanine	7.5	7.5
Aspartic acid	9.0	6.1
Glutamic acid	15.5	9.5
	36.0	26.3

From these four acids, therefore, may arise twenty-six, or nearly half of the total of fifty-eight parts, of glucose which may originate from protein in metabolism.

Speaking more strictly, forty-five per cent. of the total sugar production from protein in diabetes may arise from the four acids named, which make up thirty-six per cent. of meat protein. It is only a question of time for the attainment of a complete solution of the problem.

The chemistry of the protein molecule throws new light upon biological questions, though it does not explain life itself any more than heredity is explained by the chemistry of nucleic acid.

SOME COLLOID-CHEMICAL ASPECTS OF DIGESTION, WITH ULTRAMICROSCOPIC OBSERVATIONS.

By Jerome Alexander

Received February 16, 1910.

The changes which occur during digestion, and in fact in almost all physiological processes, are remarkable not only because of their very profound nature, but also because they are produced at comparatively low temperatures and in the presence of extremely dilute reagents. The living organism disintegrates proteins, oxidizes carbohydrates, and with the same apparent ease synthesizes substances of great complexity. Powerful reagents and high temperatures, which would be destructive to life, are necessary to bring about changes of this character under ordinary laboratory conditions.

The digestive process is preliminary to the actual absorption and use of food by the organism, and has for its object the modification or change of the ingested food into such forms or such substances as may be absorbed in the lower part of the digestive tube. To have a correct understanding of the absorption of the products of digestion, we must bear in mind the fact that the walls of the digestive tract act as semipermeable colloidal membranes, and that absorption consists in diffusion into or through these membranes or their constituent cells. Substances in crystalloidal solution, and colloidal sols whose particles are sufficiently small, represent then the two classes of digestion products which are diffusible and therefore absorbable.

Food as ingested consists mainly of substances that may be grouped into two classes:

1. Crystalloids—such as water, sugars, sodium chloride, etc.
2. Colloids—such as starch, proteins, etc.

The crystalloids are usually absorbed directly, although sucrose, for example, undergoes inversion. The colloids, as a rule, are not directly absorbable and for the most part digestion consists in the disintegration[1] of the colloidal complexes of the food, so that they can actually diffuse into the organism and there undergo further changes. Colloidal gels or even sols whose particles are of large size are, practically speaking, non-diffusible, and must therefore be reduced to a more finely dispersed state. So strong is the analogy between digestion and colloidal disintegration that Thomas Graham,[2] the father of colloid chemistry, coined the word *peptization* to express the liquefaction of a gel. He first speaks of the coagulation or pectization of colloids. "The pectization of liquid silicic acid," he states, "and many other liquid colloids is effected by contact with minute quantities of salts in a way which is not understood. On the other hand, the gelatinous acid may be again liquefied, and have its energy restored by contact with very moderate amounts of alkali. The latter change is gradual, 1 part of caustic soda, dissolved in 10,000 water, liquefying 200 parts of silicic acid (estimated dry), in 60 minutes at 100°. Gelatinous stannic acid also is easily liquefied by a small proportion of alkali, even at the ordinary temperature. The alkali, too, after liquefying the gelatinous colloid, may be separated again from it by diffusion into water upon a dialyzer. The solution of these colloids, in such circumstances, may be looked upon as analogous to the solution of insoluble organic colloids witnessed in animal digestion, with the difference that the solvent fluid here is not acid, but alkaline. Liquid silicic acid may be represented as the 'peptone' of gelatinous silicic acid; and the liquefaction of the latter by a trace of alkali may be spoken of as the peptization of the jelly. The pure jellies of alumina, peroxide of iron, and titanic acid, prepared by dialysis, are assimilated more closely to albumen, being peptized by minute quantities of hydrochloric acid."

---

[1] It must of course be borne in mind that actual chemical changes may and very frequently do accompany changes of this character.

[2] "On the Properties of Silicic Acid and Other Analogous Colloidal Substances," *Proc. Roy. Soc.*, June 16, 1864.

Investigation has demonstrated that the high efficiency of the digestive juices is mainly due to small quantities of certain colloidal substances called enzymes (such as ptyalin, pepsin, and pancreatin) which act as catalyzers, enormously hastening reactions which would otherwise proceed so slowly that, practically speaking, they would not occur at all. The enzymes appear to act by forming with the substrate a combination of unstable character, which breaks down and liberates the enzyme again to continue the operation.[1] Recently Prof. W. M.

---

[1] In an unpublished thesis presented early in 1899, and read before this section on Dec. 8, 1899, I stated as follows:

"It appears then, that all fermentations are purely chemical changes brought about by substances usually highly complex and highly nitrogenous, as analysis shows. To confirm more fully this assumption, work should be done along the lines laid down by Büchner, and the active enzymes should be isolated from all fermentative micro-organisms. In the meanwhile we may examine into the nature of the chemical action that takes place.

"There are numerous reactions which go by the name of 'continuous processes.' The decomposition of the diazo compounds by cuprous salts (Sandmeyer's reaction) is a case in point. It proceeds according to the equation $C_6H_5N : NR + Cu_2R_2 = C_6H_5R + N_2 + Cu_2R_2$, so that the process is theoretically continuous. The cuprous salt acts the part of a carrier or 'go-between,' just as do iodine, ferric chloride, aluminium chloride and many other substances under different circumstances. The catalytic decompositions of hydrogen dioxide and hypochlorous acid are apparently continuous processes, although the intermediate compounds have not been determined.

"Not alone can only a small quantity of one substance decompose a large quantity of another, but the same substance yields varied products depending on the nature

Bayliss, in his interesting monograph on "The Nature of Enzyme Action,"[1] has shown that in all probability "the 'compound' of enzyme and substrate, generally regarded as preliminary to action, is in the nature of a colloidal adsorption compound." Any one who has seen in the ultramicroscope the extremely active motion of the individual particles in colloidal solutions, can readily imagine the terrific bombardment a substance must undergo when a colloidal enzyme is concentrated on its surface by adsorption; and indeed it seems probable that enzymes actually produce their effects by virtue of their specific surface actions and the motion of their particles.

In order to find out if this idea could be verified by actual observation, I have watched, under the ultramicroscope, the action of diastase upon potato starch grains and the action of pepsin upon coagulated egg albumen.

In the first case actively moving ultramicrons in the diastase solution gradually accumulated about the starch grains, which after a time showed a ragged and gnawed margin. While the adsorption and motion of the larger ultramicrons was all that could be followed, the bright appearance of the field indicated that more numerous finer particles were present, and some apparently of intermediate size were seen.[2]

For observations on albumin, I used a dilute solution of white of egg which had been heated nearly to boiling. It was opalescent and in the ultra apparatus exhibited a field full of bright and rapidly moving ultramicrons. Upon allowing a droplet of essence of pepsin (Fairchilds, containing 15 per cent. of alcohol by weight) to diffuse in, an immediate coagulation occurred, the particles clumping into very large masses. A droplet of decinormal hydrochloric acid was then allowed to diffuse in, whereupon the large masses broke up in small groups and single ultramicrons, which once more resumed their original motion. Soon, however, the albumin particles began to grow smaller and disappear, the field all the while becoming brighter and brighter, indicating the concom-

of the 'go-between.' Ethyl acetoacetate, when hydrolyzed with dilute boiling acids, yields ketones; while if strong alcoholic potash be employed, acids are produced. The latter is not a continuous process because the potash is eliminated by combining with the acid produced; but it illustrates the point.

"Now I believe that the actions of diastase, and in fact of all other enzymes, are in the nature of continuous processes. I base this, as yet, almost entirely upon analogy, but can indicate the line of experimentation necessary to confirm the theory.

"*First*—Active enzymes must be isolated and their chemical constitution and structure investigated.

"*Second*—The constitution of the substances to be decomposed must be understood, and also the nature of the compounds they can form with the structurally determined enzymes."

[1] Longmans, Green & Co., 1908.

[2] This work will be repeated with purer enzyme and at greater dilution.

mitant appearance of smaller ultramicrons or amicrons. *In vitro* the addition of the pepsin to the opalescent albumin solution caused it to clear gradually, even at room temperature [1]

Enzymes are inactivated to a greater or less extent by shaking, heating, electrolytes, etc., all of which, as is well known, cause the coagulation of colloidal solutions and a resulting decrease in the activity of the motion of their constituent particles. Another feature of interest is that the action of enzymes is reversible, a fact that does not usually come much into evidence because of the dilution and removal by diffusion of the products formed. In cells, tissues and organs, however, changes of concentration again occur and synthetic processes may result.

One principle of colloid chemistry is of the utmost importance in digestion, namely, the protective action of reversible colloids, which stabilize or protect from coagulation irreversible or unstable colloids. Mucin and analogous colloidal substances undoubtedly have a function of this character, which may in some cases account for the variance between the action of natural and artificial digestive juices. The principle of colloidal protection[2] is in evidence in almost all physiological reactions and processes, and it is indeed extremely doubtful if there ever occurs *in vivo* any chemical reaction which is not greatly influenced by the colloids always present. How powerful this influence is, may be seen by adding hydrochloric acid to a solution of silver nitrate containing a little gelatin; instead of the usual precipitate, there results only an opalescent hydrosol which passes entirely through filter paper.[3] This directs our attention to a very important consequence of colloidal protection, namely that in the presence of protective colloids, colloidal sols pass through membranes otherwise impermeable to them.[4]

In the light of the principles outlined above, let us consider the digestion of milk, food which contains crystalloids (water, soluble salts, lactose) and colloids (casein, albumin), besides fat in suspension. The main interest centers in the proteins and in the fat, which will be considered in the order given.

The chief proteins of milk are casein and lactalbumin, both of which exist in colloidal solution. In the case of cow's milk the casein is readily coagulated by acids and by the ferment rennin, and therefore such milk curds soon after its ingestion. I will not attempt to mention the numerous and sometimes weird theories advanced to explain the phenomenon

[1] The experiment with pepsin must be repeated with purer enzyme and at greater dilution, in order to follow the course of the action more in detail.

[2] For particulars regarding "protective action," see "Colloids and the Ultramicroscope," by Prof. R. Zsigmondy. J. Wiley & Sons, 1909.

[3] For other reactions of this character, see *J. Soc. Chem. Ind.*, **28**, 280 (1909).

[4] See Zsigmondy, Chapter 14. Mucous membranes, when moistened with bile, allow fat to penetrate more readily than when not so treated (Jacobi).

of the curding of milk, most of which have been considered by Kastle and Roberts in their article on "The Chemistry of Milk."[1] Although many investigators regarded the rennin coagulation of milk as a colloidal or physical, rather than a chemical change, I was, so far as I am aware, the first to point out[2] that casein is an irreversible or unstable colloid which is protected from coagulation by the reversible colloid lactalbumin. A very simple experiment will suffice to show the significance of this fact: if we add to cow's milk some protective colloid such as gelatin or gum arabic, it becomes insensitive to quantities of acid and rennin which would otherwise produce coagulation.

Owing to the very great importance of milk as a food, especially for infants and children, the question of the digestibility of milk has for years received the closest study of the medical profession, and many facts have been established by clinical experiment. Thus, as far back as 1888, Dr. Abraham Jacobi[3] advocated the addition of gelatin and gum arabic to milk intended for infants, and in a recent paper he states:[4] "Ass's milk has always been recognized as a refuge in digestive disorders, when neither mother's or cow's milk or its mixtures were tolerated." These facts are readily understood if we look over the following table[5] showing the average constitution of various milks:

Kind of milk	Casein	Albumin.	Total proteins.	Fat	Sugar.
Cow	3.02	0.53	3.55	3.64	4.88
Human	1.03	1.26	2.29	3.78	6.21
Goat	3.20	1.09	4.29	4.78	4.46
Ewe	4.97	1.55	6.52	6.86	4.91
Mare	1.24	0.75	1.99	1.21	5.67
Ass	0.67	1.55	2.22	1.64	5.99

It will be seen that in mother's milk the casein is protected from coagulation by a much higher ratio of albumin than cow's milk, whereas ass's milk is even more highly protected than mother's milk. With such highly protected milks, the curd (if indeed coagulation does actually occur at all) is much more readily redissolved in the process of digestion.[6]

[5] Compiled by Leach from Koenig.

[6] Too low a percentage of albumin in mother's milk might make it indigestible for the infant. It is interesting to note here that Dibbelt (*Arb. Geb. path. anat. Bact.*, 6, No. 3, see C. A., 3, 2943) has shown that cases of richitis (rickets) are caused by deficient absorption of calcium, the infants not being able to utilize the larger percentage of calcium in cow's milk and artificial food.

The anomalous results of Kastle and Roberts (*Bull.* 41, 325), who found

Ultramicroscopic observation fully confirms the principle of colloidal protection above stated. Using a Leitz dark field condenser with $^1/_{12}$ oil immersion objective, and a 1200 candle power arc light for illumination, the individual particles of casein may be seen in very active motion. Upon allowing a little dilute acid to diffuse in under th cover glass, the agglutination or coagulation of the casein particles may be distinctly followed. They gather at first into groups of two or three, and gradually into larger and still larger masses. As the size of these groups increases, their motion decreases proportionately, until at last they float quietly and sink to the bottom of the fluid.

If, however, a little gelatin or gum arabic be added to the milk before the addition of the acid, the clumping is entirely prevented. The particles of casein continue the active motion, which in reality keeps them afloat and in solution.

These observations I first made on May 9, 1909, and since then they have been frequently repeated[1] For ultramicroscopic examination a very dilute solution of skim milk (one drop to 100 or 200 cc. of water) should be used, for fat globules, or too great a degree of concentration produce a confused field A very dilute solution of benzopurpurin (which dissolves as a colloid) shows exactly the same protection by reversible colloids as does milk, and in this case the macroscopic color changes as well as ultramicroscopic observation show that gelatin exercises a much greater protective action than gum arabic.[2]

Gelatin also protects casein against coagulation by rennin, as may be shown both in macroscopic and ultramicroscopic observations.[3]

Another very vital point to consider is that the colloidal protection of the casein has an important influence upon the digestion of the milk fat.

In the first place, the initial subdivision of the fat in milk is favored by the "lactalbumen," which acts as an "emulsifier." The use of colloids in forming and preserving emulsions has long been known in the arts and in pharmacy, and has also attracted the attention of physiologists. Thus Moore and Krombholz, in a paper entitled "On the Rela-

---

that frequently quite acid milks did not coagulate, whereas faintly acid milks did, are probably due to the fact that the former owed their stability to a larger relative percentage of albumin than the latter

tive Power of Various Forms of Proteid in Conserving Emulsions,"[1] state as follows:

"The action of acid and alkali albumins in so maintaining emulsions, must be of service in the digestion and absorption of fats. Protein food is invariably eaten along with fats, and as the fat becomes emulsified, it will be maintained in a finely subdivided form by the action of the acid and alkali albumin simultaneously formed. The fat does not become much subdivided in the stomach, and hence the acid albumin formed here does not come much into action, but afterward in the duodenum the alkali albumin present undoubtedly must aid in preserving the emulsion which is formed there."

The value of an emulsifying colloid is readily demonstrated by adding ferric chloride to a commercial emulsion of cod liver oil; this immediately coagulates the protective colloid and the oil at once separates out. It must also be remarked that protective colloids in the various digestive juices must be reckoned with, as well as those in the food, and those formed from the food.

In the case of milk the presence of a coagulative colloid, casein, introduces another factor, since the curd always carries down with it a very large percentage of the fat present. Now the smaller the degree of colloid protection, the greater is the probability of coagulation, and the less soluble the resulting curd. The total prevention of coagulation is highly desirable, especially in the presence of much milk fat, because fatty curds have a great tendency to adhere and form large masses which resist the action of the digestive juices.[2] In the so-called "fat indigestion" described by Czerny and Keller and others, the trouble has for the most part been ascribed to an excess of fat. But mother's milk, as a rule, contains even more fat than cow's milk, and I have heard of cases showing the typical hard, dry stools of "fat indigestion" where the child was fed cow's milk containing only 2 per cent. of fat. It would seem then that the protection of the casein is of the highest importance in favoring the absorption of the fat as well as the casein of milk.

Interesting confirmation of this is to be found by reading the results of Prof. C. A. Herter, as given in his book on "Infantilism."[1] He describes here a condition of arrested development, consequent upon the non-absorption of food and its subsequent putrefaction in the lower intestine. The patients excreted practically all the calcium ingested, this accounting for the failure of skeletal growth, and the feces contained neutral fat, fatty acids, and soaps in marked excess, indicating impaired fat absorption.[2]

---

[1] *Brit. J. Physiol.*, 22, 54 (1908).

[2] This process is well described by Dr. J. W. Schereschewsky, in his paper on "Infant Feeding," *Bull.* 41, Hyg. Lab. U. S. Pub. Health and Mar. Hosp. Service, p. 658, *et seq.*

In a recent paper entitled "Casein Curds in Infants' Stools," just published in the *Archives of Pediatrics*, 26, 924 (Dec., 1909), Dr. F. B. Talbot states in conclusion: "Furthermore there is sufficient clinical and scientific evidence to prove that tough curds are composed principally of casein, that they are due to the imperfect digestion of casein, and that an excess of casein in the food may result in a fat as well as a casein indigestion."

Herter found that the addition of gelatin (which is a most efficient protective colloid) to the milk fed, caused an improved absorption and recommends its use.[3] He further observes that "in sparing protein small quantities of gelatin appear to have about as much effect as larger amounts," a fact quite in accord with protective action, for only a small percentage of gelatin is needed to accomplish protection.

In conclusion, I would point out that bald chemical analysis cannot express the digestibility and availability of a food any more than it can express or explain the action of the digestive juices, or in fact any other physiological process. In all these processes can be traced the influence of the colloidal substances everywhere present in the body, whose effects are quite out of proportion to their small mass. Striking examples are the enzymes which catalyze and direct chemical and physical changes, and the protective colloids which oppose crystallization, precipitation and coagulation, emulsify fats, and facilitate diffusion and absorption. As soon as we approach the chemistry of living organism, we are confronted with problems of colloid chemistry, and there is no doubt but that a correct understanding and application of its principles will throw much light upon many other obscure problems in biology, physiology and medicine.

[FROM THE LABORATORY OF BIOLOGICAL CHEMISTRY OF THE HARVARD MEDICAL SCHOOL.]

ON THE ESTIMATION OF THE INTENSITY OF ACIDITY AND ALKALINITY WITH DINITROHYDROQUINONE.[4]

BY LAWRENCE J. HENDERSON AND ALEXANDER FORBES

Received March 10, 1910

Indicators serve two distinct purposes: The one is to mark sharply an end point in titration, the other to measure the concentration of ionized hydrogen or hydroxyl in solution. The properties which qualify a substance for these two uses are quite different, and usually opposite. Thus our common indicators, selected for use in titration, possess a very limited value in measuring the reaction of a solution, because they change color sharply at a particular reaction, and otherwise not at all. No other means than the employment of indicators permits the rapid estimation of reaction, and even the valuable method of Salm, wherein of necessity a large number of indicators are employed, is far from fulfilling the requirements of a quick method for approximate estimations.

[1] "On Infantilism from Chronic Intestinal Infection," by C. A. Herter, M.D. The Macmillan Co., 1908.

[2] It is now well known that the cream layer or fat of milk contains from 10 to 500 times as many bacteria as the whole milk. See (U. S. Dept. Agr.) *Bull.* 56, 737; also Jacobi, *J. Am. Med. Association, loc. cit.*

[3] Herter, *loc. cit.*, pp. 101, 105.

[4] An investigation aided by a grant from the Elizabeth Thompson Science Fund

In seeking a solution of this problem the behavior of 2,5-dinitro-hydroquinone, among other substances, has been studied, its chemical properties being such as to suggest that it might be suitable for the purpose. This substance when dissolved in distilled water, has a bright orange color which changes on addition of moderately strong acid to pale greenish yellow, and on addition of moderately strong alkali to deep purple. Evidently this wide range of colors renders it unusually well suited to the measurement of all intensities of hydrogen ion concentration.

In order more accurately to define the characteristics of the substance and to establish a color standard, the following experiments were performed: A preparation as provided by Schuchardt was twice recrystallized from water to insure purity. From this material a 0.1 molal alcoholic solution was made up and used in all experiments. Six standard solutions of constant reaction were then prepared in the usual manner from simple bases, acids and salts, either pure or mixed, in such proportions that the solutions formed a uniformly graduated scale of acidity on the one side of neutrality, and of alkalinity on the other. The composition of the solutions and their reactions are shown in the accompanying table.

Solution.	Composition.	Reaction.	Color.
A	0.10 *N* Tartaric acid	$(H^+) = 10^{-2}$	Green-yellow
B	0.058 *N* NaH_2PO_4	$(H^+) = 10^{-4}$	Orange-yellow
C	$NaH_2PO_4 : Na_2HPO_4 = 4 : 1$	$(H^+) = 10^{-6}$	Orange
D	$NH_4OH : NH_4Cl = 1 : 27$	$(OH^-) = 10^{-6}$	Brownish cherry-red
E	$NH_4OH : NH_4Cl = 37 : 1$	$(OH^-) = 10^{-4}$	Red-purple
F	1.0 *N* Na_2CO_3	$(OH^-) = 10^{-2}$	Purple

Six 250 cc. flasks were filled from these stock solutions. To each flask was then added a small constant quantity (10 drops) of the indicator solution. The colors of the solutions thus tested are given in the table. Between any two of these colors an intermediate color may readily be distinguished from either, while in those mixtures between orange and purple, where the color change is greatest, several intermediate hues may be differentiated. The indicator has been employed with a variety of salts of the alkalies and the alkaline earths and with ammonium salts, but in no case has an effect of the salt upon the color been noted which is sufficient to cause a significant error in such approximate estimations.

If the indicator be left long in a solution which is even slightly alkaline, as indicated by a reddish color in the solution, or the color of more intense alkalinity, decomposition occurs and the color fades. This destruction occurs too slowly however to cause any trouble. It should be noted that the color varies greatly with the temperature, thus the purple color of high alkalinity may be converted into almost pure blue by warming.

With the aid of this substance it is, accordingly, possible to estimate the concentration of ionized hydrogen and hydroxyl in an unknown solution rapidly and accurately to about one power of ten between hundredth normal concentration of ionized hydrogen and hundredth normal concentration of ionized hydroxyl. In all, eleven different intensities of reaction may be thus differentiated. To this end it is necessary to prepare a series of standard solutions corresponding to those above described The process then consists merely in the matching and interpolation of colors

[FROM THE RESEARCH LABORATORY OF THE ROOSEVELT HOSPITAL, NEW YORK CITY.]

THE QUANTITATIVE DISTILLATION OF AMMONIA BY AERATION.

(SECOND PAPER.)

BY PHILIP ADOLPH KOBER

Received February 24, 1910

In a previous paper[1] a new apparatus for the quantitative distillation of ammonia was described, which, since, has been tried in several laboratories. In three cases the results have been published and it is the object of this paper to summarize, and to discuss, the criticisms that have been made, and to record the experience accumulated during the past two years.

In a recent article[2] J. Sebelien in conjunction with A. Brynildsen and O. Haavardsholm developed and reported independently the identical process devised by the writer over a year before.

They proved by many experiments that ammonia can be liberated from solutions quantitatively, even if a slow stream of air and a large volume of solution (200 cc.) are employed. They concluded that the aeration procedure has many advantages over the old method and eliminates several sources of error.

Davis[3] found that the method, using an ordinary water pump, gave good results provided the flask was insulated with asbestos. He also makes the statement that if 30 cc. of acid are digested, the flask would require additional heat during distillation.

---

[1] THIS JOURNAL, 30, 1131 (1908).

[2] Read by J. Sebelien in the Section for Analytical Chemistry, Congress of Applied Chemistry, June, 1909, printed in *Chemiker-Zeitung*, 1909, No. 87.

[3] THIS JOURNAL, 31, 56 (1909).

An asbestos insulator can hardly be of any service in keeping the contents of a flask warm, while a rapid stream of cool air is passing through it. Doubtless, the good results recorded were not dependent on the use of asbestos. That 30 cc. of sulphuric acid can be handled in the process is shown by the figures of J. Sebelien and collaborators. Gill and Grindley have quite recently reported[1] favorably on the process in application to many substances but concluded that the elements magnesium and phosphorus when present together in relatively large amounts cause a slight retention (3.2 per cent.). This conclusion, based on the analysis of cottonseed, wheat bran, and magnesium ammonium phosphate, involves the assumption that magnesium ammonium phosphate, supposedly formed during the digestion, somehow or another, in the strongly alkaline solution holds back the ammonia.

According to modern views of chemistry concerning ions and their concentration it is hard to conceive of magnesium, in a large excess of sodium hydroxide, being in solution at all. In their paper they refer to Steel and Gies[2] having proven it impossible to liberate ammonia quantitatively when the urine contained magnesium and sodium carbonate, but omit to mention that these authors settled the point in question, namely, that sodium hydroxide liberates quantitatively ammonia from magnesium ammonium phosphate. They also refer to a previous paper of mine on the influence of magnesium and calcium salts in retarding ammonia distillation, but surely calcium and magnesium salts cannot come into consideration in an excess of sodium hydroxide.

The figures given by Gill and Grindley record a retention of 3.2 per cent. of the ammonia in magnesium ammonium phosphate, which means that 96.8 per cent. of the ammonia in magnesium ammonium phosphate was distilled and determinable. Taking this value and calculating the amount of ammonia that would be retained from the data given in regard to the content of magnesium and phosphorus in food, etc., we would have in the most unfavorable case a decrease of 0.02 in the per cent. of nitrogen. In order, however, to leave no doubt as to the accuracy of the preceding theoretical discussion the following comparisons[3] were made. A few of them will suffice as they have, apparently, but one interpretation.

	Old distillation with heat, etc.	Aeration after the addition of 5 grams $MgHPO_4$.
Urine No. 1	11.50	11.55
Urine No. 2	11.60	11.60
Urine No. 3	17.35	17.37

The results are expressed in terms of *n*/4 ammonia after making suitable blank determinations, using all the reagents. This amount of magnesium phosphate, being practically ten times more than is sufficient to combine with all the ammonia, does not show the slightest retention.

---

[1] This Journal, 31, 1249.

[2] *J. Biol. Chem.*, 5, 71 (1908).

[3] These distillations were made in the laboratory of Dr. C. A. Herter.

The statement by the authors that it was necessary to keep the solution warm, gives us a key to the source of error, *e. g.*, insufficient excess of alkali.

Experience with the Method.

Since the first publication nearly two years ago the writer has gained considerable experience with the method in the analysis of foods and allied products, particularly in distilling large numbers of solutions in series using but a single ordinary water pump. The time required for complete distillation of ammonia from the long-necked Kjeldahl flask (of 500 cc. capacity) is about two hours, whereas with a large wash bottle (of 700 cc. capacity) the time required is three hours. The time required for aeration varies, as Folin pointed out, with the temperature, alkalinity, volume, and height of the solution.

Saturated alkali in large excess should always be used (about 40 per cent. more than necessary to neutralize the acid). The application of an open-screw pinchcock has made it possible to control the aeration process completely in all respects. Before the addition of the concentrated alkali, this screw pinchcock is applied (at X in the original illustration) at the junction between the Kjeldahl flask and the absorption bottle and the rate of aeration reduced (about 100 bubbles a minute). As the alkali enters the Kjeldahl flask it is shaken in a rotatory fashion until all of the alkali has been drawn over. By decreasing the aeration in this manner it was possible with perfect ease to start a distillation while the contents were still quite hot.

If the aeration is closed off completely at the junction indicated above, the absorption bottle in question can easily be temporarily removed or reinserted, for the purpose of adding more acid, titrating, etc. To avoid accidents a safety valve should be inserted in the system, between the source of vacuum and the first absorption bottle, so that the Kjeldahl flasks are not exposed to too great a vacuum.

Summary of Directions.

The melt in the Kjeldahl flask after digestion is diluted with four parts, by volume, of ammonia-free water and allowed to cool to about room temperature. After connecting to the absorption bottle and reducing the rate of aeration the alkali is added, shaking the Kjeldahl flask at the same time in a rotatory fashion. Should there be any serious back pressure in adding the alkali the rate of aeration is too rapid, and therefore should be reduced to a more suitable rate. The adding cylinder (see first paper) is then disconnected, and the second distillation attached, etc.

THE DETERMINATION OF IODINE IN PROTEIN COMBINATIONS.

(SECOND PAPER.)

BY LOUIS W RIGGS

Received February 24, 1910

During the past three years the study of the iodine content of protein substances, particularly those of the thyroid gland and various thyroid extracts, has been pursued quite steadily in this laboratory with several objects in view. Besides an attempt to determine the relation, if any, of the quantity of iodine to normal and various pathological conditions of the gland, the studies have led to the establishment of certain standards, based on the iodine content, for the grading of thyroid preparations used medicinally. Fundamental to the accomplishment of the objects is an accurate method for the determination of iodine in protein combinations.

During this investigation over three hundred analyses have been made not including duplicates. About one hundred of these were of thyroid glands from as many different human beings. Over eighty were of animal thyroids from dog, beef, pig, and sheep. About sixty were of thyroid extracts such as "thyroglobulin," "thyronucleoproteid," "thyroidine," and medicinal preparations of the gland. A dozen analyses were made of tissues other than thyroid, and about sixty were of mixtures of iodide or iodate with fibrin, heart tissue, pancreas tissue, casein, or other non-iodine containing protein.

The author was led to question the Baumann process by failure to obtain any iodine in nine thyroid glands from patients whose cases were reported as exophthalmic goiter, although iodine was found in glands from twenty similar cases, and also by failure in some instances to obtain concordant results by duplicate analyses of samples from the same gland.

In my previous paper[1] it was shown that more or less of the iodine might be converted to iodate during the fusion process, and consequently not recovered by shaking out with carbon tetrachloride, if the proportion of iodate to iodide be greater than a certain amount, which is perhaps one molecule of iodate to five molecules of iodide. It was also shown that iodate left by the application of Baumann's process could be recovered by reduction.

The present paper furnishes much additional experimental evidence of the necessity for using the reduction process. The objection[2] urged against this process is considered; and analytical data are exhibited from a considerable variety of material.

The essential points of the Baumann process are given in detail in my first paper. In outline they are: fuse the protein with sodium hydroxide and saltpeter to a homogeneous melt, extract the fused mass with water, filter, acidify with sulphuric acid, and shake out with chloroform. The chloroform solution of the free iodine is matched in color by a chloroform extract of a mixture consisting of sodium sulphate, sulphuric acid, sodium nitrite, and a known quantity of iodine as potassium iodide.

---

[1] THIS JOURNAL, 31, 710 (June, 1909).

[2] Seidell, *Ibid.*, 32, 1326 (Dec., 1909).

The most important modifications of the Baumann process suggested in my first paper are: Use of carbon tetrachloride in place of chloroform. Use of 10 cc. Nessler tubes of *white* glass in which 10 cc. of liquid makes a layer 10 cm. deep. Use of a fusion extract of a non-iodine containing protein instead of plain sodium sulphate for the preparation of standards. After the completion of the analysis by Baumann's method, the acid aqueous liquid, from which free iodine had been removed, was made alkaline, reduced with Devarda's alloy, filtered, acidified with sulphuric acid, sodium nitrite added, any free iodine shaken out with carbon tetrachloride and read against standards made from the reduction products of Devarda's alloy and a known quantity of iodine.

Several investigators have reported the finding of thyroid glands free from iodine, and theories have been constructed with reference to the function of "iodine-free thyroid." In the analysis of over one hundred and eighty thyroid glands in this laboratory I have yet to find one free from iodine. If, however, I had used the Baumann process *without* the reduction feature, I could have reported more than a dozen glands as iodine-free. Table I exhibits some of these results

In Tables I, II, III, IV, and VI the figures have been calculated from the readings to milligrams of iodine per gram of fresh gland or fresh proteid. In Table V, the figures mean total quantity of iodine in milligrams in the sample used for analysis. The term "trace" wherever used in this paper means less than 0.01 mg. of iodine in 10 cc. of carbon tetrachloride. The untrained eye can readily appreciate 0.01 mg. of iodine in 10 cc. of carbon tetrachloride when looking through a column of the liquid 10 cm. deep at a white ground. Where percentages are given, traces are discarded in the calculations.

TABLE I

No	Before reduction.	After reduction	No	Before reduction.	After reduction.
1	trace	0.032	7	0.0	0 035
2	0 0	0 011	8	0.0	0.0025
3	0 0	0 013	9	0.0	0 01
4	trace	0.022	10	trace	0 034
5	trace	0 03	11	0.0	0 043
6	0 0	0.01	12	trace	0 026

Nos. 1 to 9 represent pathological human thyroids analyzed in 1907, using zinc dust as a reducing agent. It is possible that if Devarda's alloy had been used larger quantities of iodine would have been recovered. Some of these glands weighed from 150 to 200 grams so that although the weight of iodine per gram of fresh gland was small, the total quantity was in some cases equal to that frequently found in normal glands. Nos. 10 to 12 represent sheep thyroids very poor in iodine.

Seidell suggests that the iodine which I found by reduction was that left in the aqueous liquid by imperfect extraction, although in the thirty analyses reported in my previous paper I used two portions of carbon tetrachloride of 10 cc. each, while he claims complete extraction with three portions of two or three cc. each. A few careful analyses in which more iodine was found after reduction than before would be sufficient to show the error of the foregoing suggestion. In twenty-five analyses I find more than 50 per cent. of the iodine by reduction.

Again if the iodine obtained by reduction be due to imperfect removal of the free iodine by the *first* extraction with carbon tetrachloride, then the greater the quantity found before reduction, the larger the quantity left by imperfect extraction to be recovered by reduction. Table II exhibits the analytical results upon glands rich in iodine in which none or but traces were found by reduction.

TABLE II.

No	Before reduction.	After reduction	No.	Before reduction	After reduction
1	0.47	trace	7	0.36	0.0
2	0.30	0.0	8	1.67	trace
3	0.34	0.0	9	0.97	trace
4	0.70	trace	10	0.30	0.0
5	0.65	0.0	11	0.71	trace
6	1.33	trace	12	1.04	0.0

In these cases where the largest absolute quantity of iodine should be found by reduction, if Seidell's assumption be well founded, I find none or but traces.

In my previous paper it was stated that the most accurate readings were obtained when 10 cc. of carbon tetrachloride contained from 0.02 to 0.15 mg. of iodine. (It is my practice to select such an aliquot part of the fusion extract as will bring the readings within these limits mentioned.) But four of the readings of the thirty analyses of thyroids reported in that paper were above 0.15. Two were 0.16, one 0.20, and one 0.21. The average reading for the thirty was 0.11 mg. In each of these thirty analyses the acid aqueous liquid, which generally measured about 20 cc., was extracted with a second 10 cc.[1] of carbon tetrachloride to remove possible traces of iodine left by the first extraction before applying to reduction process. This detail was overlooked by Seidell in his reference to the reduction process.

In order to determine the quantity of iodine left in 20 cc. of the acid aqueous liquid after *one* extraction with 10 cc. of carbon tetrachloride the following experiment was performed: Ten cc of an iodine-free fusion extract were placed in each of six separators marked respectively *A*, *B*, *C*, *D*, *E*, and *F*. To each separator were added 0.2 mg. of iodine as potassium iodide, 1 cc. of a 1 per cent solution of sodium nitrite, 10 cc. of carbon tetrachloride, and about 7 cc. of 10 per cent. sulphuric acid which was enough to cause a strong acid reaction. The separators were then vigorously shaken with care to prevent loss by the escape of carbon dioxide. After three shakings at intervals of ten to fifteen minutes the carbon tetrachloride was drawn off from each separator as completely as possible. Ten cc. of fresh carbon tetrachloride were then added to the contents of separator *A*, thoroughly shaken, filtered into a 10 cc. Nessler tube, compared with standards and found to contain much less than 0.01 mg. of iodine. This portion of carbon tetrachloride, which had made the *second* extraction of the acid aqueous liquid in *A*, was then added to the contents of separator *B*, shaken out and added to *C* and so on until the acid aqueous liquid in each of the six separators had been subjected to its *second* extraction by the same 10 cc of carbon tetrachloride. From the last separator (*F*) the carbon tetrachloride was filtered into a Nessler tube, compared with standards, and found to contain 0.03 mg. of iodine, from which I conclude that approximately 0.005 mg. of iodine is left in 20 cc. of acid aqueous liquid, originally containing 0.2 mg. of iodine, after iodine is removed by the *first* ten cc of carbon tetrachloride. This result was obtained before the publication of my previous paper. It has since been confirmed by two repetitions with concordant results.

---

[1] THIS JOURNAL, 31, 712, line 7 and line 39.

The acid aqueous liquid in the six separators was then subjected to a *third* extraction with 10 cc. of carbon tetrachloride, performed in the same manner as the second extraction already described, and found to contain *no iodine.*

If 20 cc. of acid aqueous liquid contain *less* than 0.2 mm. of free iodine, less will be left after the first extraction thus making a second extraction quite superfluous. Experiment confirms this statement. Several samples of acid aqueous liquid containing from 0.1 to 0.15 mg. of iodine, when extracted with a second 10 cc. of carbon tetrachloride, gave a liquid that could not be distinguished from 10 cc. of the pure reagent by several observers each accustomed to colorimetric reading.

The results of the application of this process to other glands, in which the presence of iodine might be suspected, are shown in Table III.

TABLE III.

No.	Before reduction	After reduction	No.	Before reduction.	After reduction.
1.	0.0	0.0	4	0.0	0.0
2.	0.0	0.0	5	0.0	0.0
3.	0.0	0.0	6	0.0	trace

No. 1 was a thymus gland from a child one year old, 2 and 3, thymus glands from adults, 4 and 5, beef parathyroids, and 6 a human hypophysis. The record exhibited in Table III at least serves as a check on the purity of the reagents used in this investigation.

The analyses shown in Tables IV and V were made by Miss Van Alstyne of this laboratory and to whom I wish to express my thanks. The determinations of iodine recorded in Table IV were incidental to physiological studies on the storing of iodine in the thyroid gland by dogs; and those of Table V to the standardizing of thyroid preparations used medicinally.

TABLE IV

No.	Before reduction	After reduction	No.	Before reduction.	After reduction.
1	3.59	0.0	6	trace	0.50
2	0.87	0.0	7	0.05	0.03
3	0.46	0.0	8	0.06	0.19
4	9.32	0.0	9	0.52	0.17
5	4.37	0.0	10	0.25	0.16

Twenty-four other determinations of iodine were made in the course of this investigation, fourteen of which gave other 5 per cent. of the iodine by reduction, while four gave all of the iodine *before* reduction. The extremely large quantities of iodine in Nos. 1, 4, and 5 were produced by previous iodine feeding.

TABLE V

No.	Before reduction.	After reduction.	No.	Before reduction	After reduction.

2	trace	0.18	5	0.38	0.025
3	trace	0.02			

Table VI shows the results of the analysis of various fractions of human thyroproteins by Dr. Beebe whom I again wish to thank for many favors.

TABLE VI.

No.	Before reduction.	After reduction.	No.	Before reduction.	After reduction.
1	0.68	0.19	4	0.30	0.43
2	0.80	0.20	5	0.27	0.18
3	0.22	0.39			

The figures exhibited in Tables IV, V, and VI clearly demonstrate that when 10 cc. of carbon tetrachloride are used with about 20 cc. of the acid aqueous liquid, imperfect extraction of iodine as suggested by Seidell in no way accounts for the results.

A partial summary of the author's work on the determination of iodine in the thyroid presents the following points: 14 out of 40 glands containing *more* than 0.25 mg. of iodine per gram of fresh gland gave above 5 per cent. of their iodine by reduction. Average of the 14 was 14.2 per cent. 38 out of 59 glands which contained *less* than 0.25 mg. of iodine per gram of fresh gland gave above 10 per cent. of their iodine by reduction. Average of the 38 was 55.2 per cent. Excluding from the 38, 13 glands which gave all of their iodine by reduction and the average percentage of iodine obtained by reduction from the remaining 25 glands was 31.9 per cent While this summary emphasizes the necessity of applying the reduction process to glands poor in iodine, particular analyses show that glands rich in iodine may sometimes yield a considerable quantity of their iodine by reduction.

The experimental results of this paper thoroughly confirm the statement of my previous paper, namely: that more or less iodate is usually present and that in an accurate determination of iodine in protein combinations it is never safe to omit the reduction feature. These results are not explained by the statement "at extreme dilution the constancy of distribution coefficients disappears," which Seidell invokes.

In attempting to follow Seidell's interpretation of Baumann's process, I find it impossible to be certain of several details. Seidell refers to Baumann's earlier process,[1] instead of his later improved process.[2] A very important and essential part of the process as described in both of Baumann's papers is made optional, thus, Seidell directs, "If much charred organic matter is present a little sodium nitrate may be added," etc., from which one would infer that the addition of a nitrate during the fusion is not required, and in the absence of "much charred organic matter" unnecessary. I find a loss of about one half the total iodine to follow the omission of nitrate during the fusion process in two analyses of sheep thyroid rich in iodine.

Baumann, Oswald, Anten, Marine and Wells, working with similar quantities of protein material to those used by Seidell, employed 10 cc. of solvent (chloroform or carbon disulphide) to extract the iodine from the acid aqueous liquid. If this liquid be extracted with only two or three cc. of solvent instead of 10 cc , it would be expected that a considerable portion of iodine would remain to be extracted by further applications of fresh solvent. Although it is well known that two portions, say 5 cc., of solvent successively applied will dissolve slightly more solute than one portion of 10 cc., it is not clear wherein three successive applications of 2 or 3 cc. of solvent confers accuracy upon this process, especially in view of the fact that one application of 10 cc. of solvent removes 97.5 per cent. of the iodine from the maximum concentrations used by the present writer.

The statements by Seidell that "the reduction process as suggested by Riggs leads to greater errors in the determination of iodine than are inherent in the Baumann process" and "any iodine not removed before the reduction process leads to a positive error" are totally unsupported by experimental evidence.

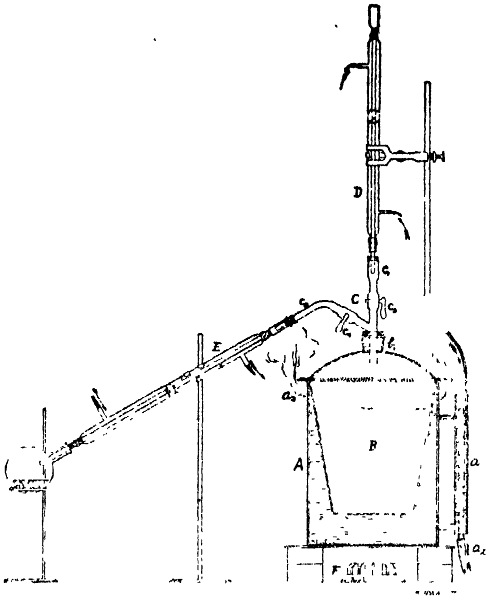
AN APPARATUS FOR ABSOLUTE ALCOHOL.

BY W. H. WARREN.

Received March 12, 1910.

Freshly prepared absolute alcohol is more reliable than the article supplied by dealers and much cheaper. One never feels quite sure without making a test that he is getting an alcohol which is really absolute. For preparing small quantities of this solvent there is no need of suggesting any modification of the usual procedure of boiling ordinary alcohol over burnt lime in a glass flask under a return-condenser and distilling. But large classes of students often require considerable absolute alcohol, the preparation of which has to be left to persons more or less inexperienced. Under these conditions there is frequent breakage of glass together with loss of alcohol, and another form of apparatus is desirable. For some time the apparatus shown in the drawing has given satisfactory results in this laboratory. It is constructed of copper and was made according to specification by the firm of Eimer and Amend, New York. A tinsmith can make a less expensive apparatus of heavy tin which will answer every purpose.



The outer flanged copper vessel *A* has an inside diameter of 28 cm. and is 30 cm. high. It is tinned on the inside and the bottom is reinforced on the outside with iron for protection against heat. This vessel serves as a water-bath in which water is kept at constant level by means of the side tubulus a_1 provided with the overflow pipe a_2. The water which passes through condenser *D* runs into a_1. Several openings a_3 at the top allow steam to escape. This bath rests upon bricks and heat is applied from the Fletcher burner *F*.

Within *A* and resting quite free upon its flange is a second flanged copper vessel, *B*. Except for the opening b_1 for introducing burnt lime and alcohol, this inner vessel is closed. It is 24 cm. in diameter and 28 cm. high to the flange. The diameter of the opening b_1 is 57 mm. When filled with burnt lime, *B* holds about nine liters of commercial grain alcohol.

A brass Y-tube *C* passes through a rubber stopper in b_1. The arm c_1 is straight and somewhat widened at the top to admit the rubber stopper connecting it with condenser *D*, but the arm c_2 is bent at an obtuse angle. On each arm beyond the point of divergence is a cock c_3 and c_4. The internal diameter of these tubes is 15 mm., but a somewhat larger bore would be an advantage. Of especial importance is the bore of the cock which should be the same as that of the tube. If the bore of the brass tube is too small, or the cock has a smaller bore than that of the tube, alcohol will collect in the condenser during dehydration.

Condenser *D* is connected with the top of c_1 by a rubber stopper. It should be long enough to cool well during dehydration and its bore should not be too small. Condenser *E*, connected with c_2 by a rubber stopper, is in the usual position for distilling

By closing cock c_4 and opening cock c_3, alcohol can be boiled until dehydrated. It is well to watch the apparatus closely until boiling proceeds quietly. If heated too rapidly, or if the still is too full, alcohol is apt to start boiling so violently that it will be ejected from the top of the condenser. But this occurrence can be avoided by raising the temperature gradually. When boiling begins, the flame can be adjusted and further attention is unnecessary.

By closing cock c_3 and opening cock c_4, a test portion of alcohol may be distilled at any time and its specific gravity determined. If dehydration is incomplete, the test portion may be returned through the top of the condenser. By reversing the cocks, boiling may be continued until a sample having a satisfactory specific gravity is obtained. Finally, when dehydration is complete, distillation may be begun without first cooling the alcohol. Of course all precautions should be taken to keep the distillate from absorbing moisture from the air.

A change in the construction of the still, which would probably be an improvement, may be suggested. When distillation begins and for some time after, alcohol comes over readily, but toward the end it distils slowly. Undoubtedly this is due to the size of the still, which, though well heated on the side and bottom, is not so on the inside. If four or five tubes, closed at the upper and open at the lower end, were to project from the bottom into the interior of the still, the boiling water in these tubes would convey heat into the mass of alcohol and lime and hasten distillation.

Several experiments were made with this apparatus to determine how long to boil alcohol over lime before distilling. I have heard instructors advise half an hour's boiling as sufficient, whereas others have insisted that boiling over lime should be continued for a day at least. The tests I have made with this apparatus would seem to indicate that the longer rather than the shorter boiling is advisable. In making these tests there was no intention of entering upon an investigation of absolute alcohol, but merely of determining the proper conditions for preparing absolute alcohol for laboratory purposes so that definite directions might be given to an assistant having charge of such work.

A pycnometer holding 50 cc. was used in determining all specific gravities. The weight of pure water at 15° C. was first determined in this apparatus and then the weight of an equal volume of alcohol at the same temperature. Specific gravities were compared with those given by Squibb and percentages were calculated from his tables.

Experiment 1.—Small pieces of burnt lime were put into the still to within an inch of the flange, and covered with nine liters of commercial grain alcohol. This alcohol is said to contain 188 per cent. of proof spirit. Its specific gravity was found to be 0.8198 (= 91.04 per cent. by weight). Before being heated, the alcohol stood in contact with lime for twenty-four hours. At the end of that time heat was applied and from the moment the alcohol began to boil, a test portion (about 250 cc.) was distilled every fifteen minutes and its specific gravity determined. The results of these tests are given in the following table:

No	Time of boiling in hours.	Sp. gr at 15° by pycnometer.	Per cent of alcohol by weight
1	0.25	0.7988	98.41
2	0.5	0.7972	98.91
3	0.75	0.7965	99.13
4	1.0	0.7958	99.35
5	1.25	0.7952	99.55
6	1.5	0.7950	99.61
7	1.75	0.7949	99.65
8	2.0	0.7945	99.77

Most of the alcohol after the eighth sample, which contained 99.77 per cent., was distilled into a large bottle. Its specific gravity was 0.7943 (= 99.84 per cent.). The final 500 cc. of alcohol was collected by itself and had a specific gravity of 0.7940 (= 99.94 per cent.). Nine liters of 91.04 per cent. commercial grain alcohol usually yield about six liters of absolute alcohol which will vary slightly in strength depending upon the length of time the alcohol is boiled over lime. From these tests the conclusion was drawn—and this conclusion was confirmed by later tests—that two hours' boiling is by no means sufficient to get the best possible absolute alcohol.

Experiment 2.—Nine liters of commercial alcohol were placed in the still with lime, and boiled for two hours without being allowed to stand as in the first experiment. At the end of that time a sample of alcohol was distilled and tested. This was repeated at the end of each succeeding hour and the results are given in the following table:

No	Time of boiling in hours	Sp gr at 15° by pycnometer	Per cent of alcohol by weight
1	2	0.7964	99.16
2	3	0.7954	99.48
3	4	0.7944	99.81
4	5	0.7943	99.84
5	6	0.7942	99.87
6	7	0.7942	99.87
7	8	0.7942	99.87

The experiment had to be stopped at the end of the eighth hour The remainder of the alcohol stood in contact with lime about 30 hours when boiling was resumed. At the end of an hour's boiling a sample was taken and found to have sp. gr. 0.7942 (= 99.87 per cent.). From this experiment it would appear that when the alcohol reaches the point where it gives a distillate containing 99.87 per cent., it remains constant. This point in this experiment was reached after six hours' boiling. Yet the mass of the alcohol shows a higher percentage, for most of the alcohol as in the first experiment was collected in a large bottle and had a specific gravity of 0.7940 (= 99.94 per cent.). The final portion of distillate was collected by itself but its specific gravity was the same as that of the main sample.

Experiment 3.—The two preceding experiments show that alcohol after twenty-four hours standing over lime will give a distillate at the end of two hours' boiling, containing 99.77 per cent.; whereas the same alcohol that has not stood will give, after being boiled two hours, a distillate containing 99.16 per cent. This seemed to indicate that previous standing over lime might be of advantage. This experiment was made to see if this is the case.

Nine liters of alcohol stood over lime twenty-four hours. At the end of that time the alcohol was boiled two hours and then tested A test was also made at the end of each succeeding hour with the results given in the following table:

No	Time of boiling in hours	Sp gr. at 15° by pycnometer	Per cent. of alcohol by weight
1	2	0.7952	99.55
2	3	0.7950	99.61
3	4	0.7943	99.84
4	5	0.7942	99.87
5	6	0.7942	99.87

From this experiment it would appear that alcohol, which has previously stood over lime, can be brought to the point where it will give a distillate having a constant specific gravity sooner than it can if not allowed to stand; but the difference in time is so slight that there is no advantage in the previous standing.

Experiment 4.—The quantity of burnt lime in the preceding experiments is much in excess of that theoretically needed to take up the water present. Consequently, the yield of absolute alcohol is not as high as it would be if less lime were used. In the hope of increasing the yield without lowering the strength of the alcohol, I made two tests conducting dehydration in two stages and each test gave essentially the same result.

Nine liters of commercial alcohol were boiled for six hours over 2100 grams of burnt lime. This is slightly more lime than is required to take up the water. The specific gravity of a sample of alcohol at the end of six hours' boiling was 0.8006 (= 97.83 per cent.) and that of the entire distillate was 0.7980 (= 98.66 per cent.). The total distillate measured 7450 cc.

I then returned the 7450 cc. of partially dehydrated alcohol to the still with 300 grams of burnt lime, a quantity slightly in excess of that theoretically needed to combine with the water. The specific gravity of the total distillate after six hours' boiling was 0.7970 (= 98.97 per cent.) and it measured about 7300 cc.

The yield of absolute alcohol by this method is much better but twice as much time is required and the alcohol, though sufficiently good for most purposes, is by no means as nearly absolute as it is after one treatment with a large excess of lime.

Summary.

1. It is not possible to deprive commercial alcohol of all its water by boiling over lime. Dehydration takes place gradually up to a certain point and it is useless to boil longer under return-condenser when the test-distillate contains 99.87 per cent.

2. Commercial alcohol can be brought to the point where it will give a test-distillate containing 99.87 per cent. by boiling six hours without previous standing over lime; or, by boiling five hours, after allowing the alcohol to stand for twenty-four hours over lime.

3. When the test-distillate contains 99.87 per cent., the alcohol, if distilled, will contain as a whole 99.94 per cent. I have never succeeded in getting a distillate containing a higher percentage of alcohol than this.

4. It is possible to increase the yield of absolute alcohol by conducting the dehydration in two stages and using each time a quantity of lime only in slight excess of that theoretically required to combine with the water present. But the absolute alcohol obtained will by no means be as strong as it will be if dehydration takes place at one operation in presence of a large excess of lime.

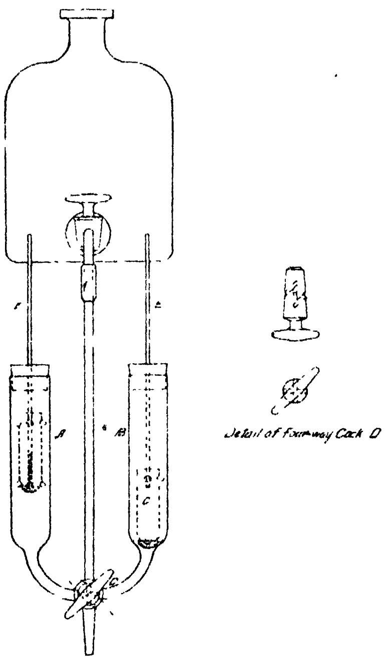
NOTE.

An Adjustable Automatic Burette.—While working at the Minnesota Experiment Station in 1906 on a large number of nitrogen determinations, it was found that the method of measuring the acid and alkali was slow, inaccurate, and not at all neat. The need of something of an automatic nature was felt, but nothing could be found in any of the catalogues of apparatus.

Work was started on a device which would be automatic and also adjustable. The first ones which were made according to drawings failed in the second requirement. However, the idea was not abandoned, and early this year a new form of float was conceived. This solved the difficulty effectually.

Two of the burettes have been at work in this laboratory for some time. One measures 20 cc. of concentrated sulphuric acid and the other 50 cc. of concentrated sodium hydroxide. They have made some 700 measurements very successfully. The percentage of error is so small as to be disregarded.

Since devising the above apparatus, there have come to my notice descriptions of two automatic pipettes. One devised by H. S. Bailey was described and illustrated in THIS JOURNAL.[1] However, it is not adjustable and allows of greater error in measurement. The other is by Professor G. E. Patrick and fully described in Bulletin 19, Iowa Agricultural Experiment Station, November, 1892. This one is adjustable, but to only a limited extent.



Adjustable Automatic Burette Pat Appld for
J O Rose inventor

Believing that the burette herein described does not possess the faults above mentioned, I herewith submit it with the hope that it may find general use in laboratories, creameries, and, perhaps, in some manufacturing establishments.

By referring to the figure, it is seen that the construction is very simple.

---

[1] 30, 1508 (1908).

Two tubes are connected at their lower extremities by a four-way stopcock, *D*, to the supply tube above and the delivery tube below. This stopcock is bored in such a way that the exit of a hole is 90° from the entrance. 90° further around is the entrance of the other hole, which, in turn, is the same distance from its exit. In this way each passage can be made to communicate with either side, *A* or *B*, of the burette by merely turning the stopcock one-quarter turn to the right or left. The position of the hole, or passages permits of the filling of one side and the emptying of the other simultaneously, so that while one charge is being delivered another is being measured.

Control of the liquid is secured by means of open floats, *C*, containing a small quantity of mercury, which act as a seal on the bottom of the glass tube, *E*. These tubes, *E*, allow the passage of air to and from the burette They are adjustable up and down and permit of the calibration of the burette to such quantities as may be desired within the limits of the burette.

The liquid is taken out of the supply bottle by means of a siphon or a tubulature at the bottom. In either case a stopcock is interposed between the supply and the burette merely as a means of safety.

The apparatus is by no means flimsy and can be made for a reasonable price, within the reach of any laboratory. It is the intention, also, to adapt the apparatus for industrial work where it is required to mix definite volumes of liquids repeatedly. J. D. Rose.

REVIEW.

RECENT WORK IN BIOLOGICAL CHEMISTRY.

By Carl L. Alsberg.

Received March 5, 1910

Four years ago, in This Journal, P. A. Levene began his résumé of biochemical literature with the statement that work in biochemistry had enormously increased. This is true to a very much greater degree to-day, as is evidenced by the establishment since Levene wrote of three new journals: *viz.*, *Zeitschrift fur Biochemie*, *The Biochemical Journal*, and the *Journal of Biological Chemistry*, though one of the old journals (*Hofmeister's Beiträge*) has been merged with the first of the three. It will therefore be utterly impossible in the space at my disposal to consider more than a fraction of the important publications which have appeared since Levene's review. One of the notable factors in this enormous increase in biochemical work is the tendency of organic chemists again to take for the subject matter of their research substances occurring in living things, as was the custom more than a generation ago before the great expansion of synthetic organic chemistry. Therefore the last years are characterized by the determination of the constitution and sometimes by the synthesis of bodies already known rather than the discovery of new bodies. This is particularly true of protein chemistry. No new ultimate component of protein has been discovered despite the calculation of Osborne, Leavenworth and Brautlecht that about 14 per cent. of the nitrogen is still unaccounted for.[1] Abderhalden, Levene, and Osborne with their collaborators, as well as others, have continued to make us acquainted with the amino acids of a large number of proteins; but their hydrolyses have not led to the discovery of any new amino acids. The important fact has come to light that some amino acids are absent in some vegetable proteins. Rye, wheat, and barley gliadin and zein lack lysine and are poor in arginine and histidine, while zein also lacks glycocoll and tryptophane.[2]

The old problem as to whether homologous proteins from different species are chemically identical, has again been attacked, chiefly by Osborne and to a less degree by Abderhalden. The method consisted in determining as quantitatively as possible the amino acids obtained on hydrolysis and comparing the results. Osborne and Clapp[3] compared the gliadin from wheat, rye, and barley, and found them very similar, corresponding to the close genetic relationship of these plants. On the other hand Osborne and Heyl[4] found that the legumin from the veitch and pea are probably not identical. Abderhalden and Schittenhelm chose the caseins from different milks and found that in cow's, goat's and probably also in woman's milk the component amino acids are so similar quantitatively and qualitatively that one is not justified from these data alone in concluding that there is any difference.[5] Now it is very probable from more purely biological considerations that some proteins which yield the same amino acids on hydrolysis, must nevertheless be different. It appears that sometimes it is not enough to know the component amino acids. It is necessary to know also the ways in which they are linked together. Fischer and Abderhalden,[6] Abderhalden[7] and also Skraup[8] have approached this question by the method of partial hydrolysis. A protein, the products of which on complete hydrolysis are known, is partially hydrolyzed. The products of this partial hydrolysis are separated and each is then hydrolyzed by itself. Thus some notion may be gained of the ways in which the component amino acids are linked. In this fashion Abderhalden[9] obtained from edestin a body yielding glutaminic acid and tryptophane, another yielding glutaminic acid, tryptophane and leucine, and a third yielding tyrosine, glycocoll and leucine. From elastin he obtained *l*-leucyl-*d*-alanine. The isomer of the latter had previously been obtained by Fischer and Abderhalden.[6]

While these studies have not led to the discovery of new amino acids, F. Ehrlich has shown that both normal and isoleucine occur in nature, the latter especially in plants.[10] This discovery grew out of important researches carried out by Ehrlich[1] and H. Pringsheim[2] independently culminating in the proof that amyl alcohol produced by yeast in fermentation was not the product of carbohydrate fermentation at all but of the protein metabolism of the yeast cell. The latter if offered leucine as a source of nitrogen deamidizes it, utilizing the ammonia to build up its own protein and excreting amyl alcohol. The fact that both *n*- and isoleucine occur, accounts for the formation of both *n*- and isoamyl alcohol. Somewhat similar conditions have been demonstrated for the *B. proteus* by Naviasky.[3] Ehrlich[4] was able to use his discovery in splitting racemic amino acids by partial fermentation with yeast in sugar solution. He thus isolated *d*-leucine, *d*-alanine, *l*-valine, *d*-phenylalanine, *d*-serine, and *l*-*a*-aminophenylacetic acid, the latter being new.

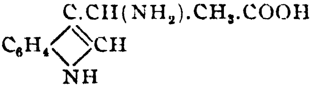
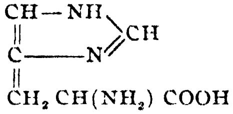
Among the known substances the constitution of which has been cleared up is tryptophane. It has been shown to be[5]



$$\begin{array}{c} C.CH(NH_2).CH_3.COOH \\ C_6H_4\langle\rangle CH \\ NH \end{array}$$

and the racemic form has been made synthetically. Furthermore Pauly,[6] Knoop and Windaus,[7] and Knoop[8] have proved that the formula of histidine is



$$\begin{array}{l} CH-NH \\ \| \qquad \quad \rangle CH \\ C-\!\!-\!\!-N \\ \| \\ CH_2\,CH(NH_2)\,COOH \end{array}$$

and Windaus and Vogt[9] have made progress in its synthesis. It will be noted that histidine is an imidazole derivative, a fact that is particularly significant if we recall that Pinner long ago showed[10] that an imidazole complex occurs among the alkaloids in pilocarpine. The discovery of the imidazole group in proteins gains further significance from the fact that Knoop and Windaus[11] have found that by the action of ammonia upon glucose imidazole derivatives are formed. E. Friedman[12] cleared up the constitution of adrenaline (epinephrine, suprarenine) and advanced far in its synthesis as did also Stolz. Stolz and Flächer finally succeeded in making *dl*-adrenaline synthetically. The commercial importance of this substance has greatly stimulated studies along these lines, which are recorded mainly in the patent literature. Recently Flächer[13] has succeeded in separating the synthetic product into its *d*- and *l*-components

by means of the acid *d*-tartaric acid salt. Cushny,[1] H. Mayer and Loewi,[2] and Abderhalden and Müller[3] have studied the isomers and have shown that the *l*-adrenaline is the most active; *d*-adrenaline is so much weaker that its activity might possibly be due to contamination with *l*-adrenaline, a striking instance of how slight differences in constitution may condition enormous differences in physiological action. *dl*-Adrenaline is intermediary.

Constitutional studies have, however, not been limited to bodies of unknown conformation. E. Fischer, in order to get easily by synthetic means material for his syntheses of polypeptides, has been driven to devise new methods for the synthesis and the characterization of well known amino acids. In this work he was confronted with the possibility of intramolecular rearrangements such as were first described by Walden. As long as there is a possibility of such rearrangements there can be no certainty that synthetic amino acids actually have the constitution to be expected from the method of preparation. It therefore became necessary to determine the conditions under which these rearrangements take place. The study of a series of amino acids led to the conclusion that this phenomenon is a most complex one, to be understood only on the basis of extensive experimental data[4] which he has since been engaged in supplying. For the present all conclusions as to the constitution of new bodies derived by substitution of the asymmetric carbon must be regarded as provisional.

With the increased ease of obtaining amino acids as the result of these and earlier similar studies by Fischer and his school, it became possible to link together amino acids in the same way in which they occur in proteins. In this way an octadecapeptide of a molecular weight of 1213 was made, the constitution of which is absolutely clear. Still larger molecules might easily be made.[5] These bodies, obtained by condensation of two or more amino acids, and known as polypeptides, were also found naturally. Fischer and Abderhalden[6] found glycyl-*d*-alanine among the products of hydrolysis by acids, while Levene at nearly the same time and independently found glycyl-proline among the products of digestion.[7] This was followed by the discovery by Fischer and Abderhalden[6] of a tetrapeptide which could be salted out with ammonium sulphate like an albumose. Fischer[8] succeeded in making synthetically a tetrapeptide resembling it in every way except that it can not be salted out with ammonium sulphate. It would therefore seem that not merely is tyrosine necessary to give these peptides an albumose character, but it must also occupy a definite position. Thus Fischer's tripeptide, *d*-alanyl-glycyl-*l*-tyrosine, can be salted out by ammonium sulphate,[9] while its isomer glycyl-*d*-alanyl-*l*-tyrosine prepared by Abderhalden and Hirzowski[10] cannot. The preparation of this type of peptide, containing hydroxyamino acids, presents great difficulties because of the sensitiveness of the hydroxyl. Fischer overcame this difficulty by the introduction of a carbomethoxy group into the hydroxyamino acid.[1]

These more purely chemical studies, resulting in a better understanding of the cleavage products of protein, have reawakened interest in the old question as to the possibility of the synthesis of protein in the animal organism. As long ago as 1902 Loewi showed that a dog could be made to retain nitrogen when fed upon carbohydrate and pancreas autolyzed to the disappearance of the biuret reaction. The inferences which should be drawn from this evidence were not accepted at once; but to-day, due to the work of Abderhalden and Rona,[2] Henriques and Hansen,[3] Lüthje[4] and others, it may be regarded as settled that the dog is able to maintain nitrogen equilibrium by means of the biuret-free cleavage products of a single protein or better still of a mixture of proteins. It seems to be immaterial whether the cleavage is carried out by autolytic enzymes already present, or by the addition of peptic or tryptic enzymes, or whether it is carried down to the simplest amino acids. It is probable that a considerable variety of amino acids must be present, which offers an explanation for the well-known fact that gelatin is incapable of replacing the ordinary food proteins, for Kauffmann[5] was able to maintain nitrogenous equilibrium upon a diet containing no ordinary protein but in its stead gelatin, together with the cystine, tyrosine and tryptophane which gelatin lacks. Nitrogen equilibrium can, however, be maintained upon protein cleavage products only when carbohydrates are also fed; not when they are absent and replaced completely by fat,[6] a fact which finds its analogy in plants in the synthesis of asparagine to protein which takes place only in the presence of starch. However, even in the presence of carbohydrate, protein regeneration is impossible from the cleavage products obtained by hydrolysis with strong mineral acids, probably because of secondary decompositions and racemizations. Still more recently Abderhalden, Meszner and Windrath[7] by feeding dogs casein far hydrolyzed with pepsin and trypsin were able not merely to maintain nitrogen equilibrium, but also to cause nitrogen retention. As regards the herbivora we are still in the dark. There is as yet no evidence that they regenerate protein from crystallizable amino acids; but this question has interested investigators less than the problem whether herbivora are able to synthesize protein from the amides which form so important an element of their food and which in some instances (asparagine) are, for herbivora, excellent protein sparers. M. Müller,[8] Völtz,[9] and Lehmann[10] believe they have demonstrated this protein synthesis, while Friedländer,[1] Kellner[2] and others hold the opposite view. Morgen, Berger and Westhausen[3] in studying the effect of amide nitrogen upon milk production conclude that it is not able to replace protein.

These views have led to endeavors to learn just how far the proteins are split in the gut, and in what form they are absorbed in consequence. Is it necessary for each protein to be split completely into amino acids, or is only a portion of the amino acids removed leaving larger complexes like polypeptides? The most recent evidence speaks for the latter possibility. There is in fact no evidence that all proteins must necessarily be split before they can be utilized; there is much against this view. Fischer and Abderhalden[4] have long since shown that neither tryptic nor peptic digestion, nor both combined, are able to split protein to such an extent that all the polypeptides disappear. In a series of researches Abderhalden and London, Abderhalden, London and Renveelin,[5] Abderhalden, Medigreceanu and London[6] have endeavored to learn just how far digestion proceeds in the different sections of the gut. These researches have not yet been entirely completed, but it has been shown after feeding edestin, casein, and egg albumin, that the amount of material precipitable with phosphotungstic acid rapidly diminishes as the food passes down into the lower sections of the intestines. The amount of tyrosine in this precipitate is very slight even in the upper sections of the intestines, while glutaminic acid is very much more slowly split off. It is present in the phosphotungstic acid precipitate from the contents of the lowest parts. All this is in harmony with the fact long known that some proteins fed to excess may appear in blood and urine in small amounts. It has furthermore long been known that proteins introduced intravenously or parenterally may be utilized, phenomena that have more recently been reinvestigated by Lommel.[7] Freund[8] and Borchardt[9] have endeavored to explain the seeming discrepancy between the fact that proteins introduced parenterally or intravenously are utilized, apparently directly, and the fact that those introduced *per os* are first more or less split. Freund[10] believes that the intervention of the intestines is necessary in order that during hunger protein may be decomposed, while Borchardt[10] was able to show that parenterally introduced elastin albumoses which are easily distinguished from other albumoses, actually accumulate in the intestinal wall. According to this view the conversion of one body protein into another requires the intervention of the intestines, a view in harmony with the theory that protein cleavage is a necessary preliminary to protein synthesis. Thus the view is gaining ground that the intestines are not merely the seat of protein cleavage and subsequent

absorption of the cleavage products, but also of protein regeneration. The question how far the proteins are regenerated within the intestinal wall still remains open. Older observers, and more recently Freund[1] and Borchardt,[1] were able to demonstrate albumoses and peptones in the blood, whereas Morawitz and Dietschy[2] were unable to do so. Upon the decision of this question hinges very largely Abderhalden's conception of protein metabolism [3] Within the gut the proteins are split more or less. In the intestinal wall protein is regenerated—not the protein of the tissues, but of the blood plasma. From the latter the tissues form their specific proteins.

These ideas give us no notion of the mechanism by which proteins are formed from crystalline material; and of course nothing but surmises can be offered upon this point. Still Taylor[4] and Robertson[5] have shown that their synthesis by enzyme action is possible. Taylor[1] took the pure amino acids obtained from protamine in concentrated solution and allowed trypsin to act upon this mixture. After some months he was able to obtain a small amount of material which had the same physical characteristics as, and the empirical formula of, the original protamine. Whether it was identical or merely isomeric with it was not determined. On the other hand Levene and Van Slyke[6] have brought forward evidence that plastein, supposed to be produced by the action of trypsin upon albumose, may be nothing but albumose and not native protein.

These advances have not been without their influence upon the investigation of pathological protein metabolism. Abderhalden and Samuely,[7] Falta and Langstein,[8] Garrod,[9] Neubauer,[10] and others, have made interesting studies upon the metabolism in alkaptonuria. The latter depicts normal metabolism as follows: The protein molecule is split within the organism mainly into amino and diamino acids. By oxidation and deamidization the amino acids are converted into the corresponding keto acids. The keto acids of the aliphatic series are converted by cleavage of carbon dioxide and oxidation into acids with one less C-atom. Their subsequent oxidation follows known laws. Of the aromatic amino acids tyrosine is first converted into the corresponding keto acid, which is oxidized to the corresponding quinol and then converted into hydroquinonepyrotartaric acid. The latter, after splitting off carbon dioxide, is oxidized to the next lower acid, homogentisinic acid. By further oxidation the benzene ring is opened and acetone bodies appear which are burned to carbon dioxide and water. Phenylalanine is converted either into phenylpyrotartaric acid or into tyrosine and then into *p*-hydroxyphenylpyrotartaric acid. It is then oxidized like tyrosine. In alkaptonuria only the oxidation of tyrosine and phenylalanine is disturbed, proceeding only to homogentisinic acid. The method of oxidation of tryptophane is not known.

Wolf and Marriott,[1] Wolf and Shaffer,[2] Williams and Wolf,[3] Simon,[4] and Garrod[5] have in part confirmed, in part modified and added to the views of Alsberg and Folin[6] on cystinuria. The view of Loewy and Mayer[7] that more than one form of cystine exists has not been confirmed.[8] It is possible that discrepancies are due to the occurrence of tyrosine in some urinary cystine stones.[9]

While all these advances in protein chemistry, however important, are but continuations and elaborations of older lines of work, this is not so for the chemistry of the fats and lipoids. Their study, which had flagged, has received a powerful stimulus because of the renewed interest in the chemistry of the nervous system; because of the theory advanced by Overton and H Mayer that the lipoids are involved in the mechanism of the action of the indifferent narcotics; because of the view, now pretty general, that the lipoids are an important element of the cell-membrane; and finally because it has been shown that they are an important factor in some of the phenomena of hemolysis and immunochemistry. The upshot of this activity has been, curiously enough, to win posthumous recognition for the work of Thudichum.[10] The majority of the substances isolated by him have to-day a definite status.[11] The animus which seems to have crept into these most difficult studies from the beginning still remains, being concentrated in two discussions. The first involves the chemical unity of protagon. This is maintained by Wilson and Cramer[12] but denied by Rosenheim and Tebb,[13] a confirmation of Lesem and Gies,[14] and a long series of investigators reaching as far back as 1874 (Thudichum) The general drift of opinion seems to be to regard it as a mixture. The second subject of polemic is intimately associated with the protagon question. It concerns the identity of cerebrin, cerebron, pseudocerebrin, and phrenosin. Chiefly concerned in it have been Posner and Gies[15] and Gies[16] maintaining the identity of cerebron and phrenosin, and Thierfelder[17] denying it. It is

probable that they are identical, and incidentally Posner and Gies have also offered evidence for the heterogeneous nature of protagon. It is evident, therefore, that despite the renewed interest in the brain, this, the most difficult field of all biochemistry, still needs a tremendous lot of cultivation. Perhaps the most important fact that has as yet appeared is the existence of highly unsaturated fatty acids in the molecule of some of the brain lipoids. Lecithin, more usually studied in egg-yolk than in the brain, may of course contain oleic acid. A still more unsaturated acid can be obtained from the lipoid kephalin, Thudichum's kephalinic acid, which is so oxidizable that it has not yet been obtained pure.[1] Physiologically the presence of these oxidizable substances in the brain is significant. They help to make brain chemistry complex, a difficulty which is further increased by the probable occurrence of stereoisomers of the commoner acids of which a larger variety is present in the brain than was formerly supposed. Fränkel obtained lauric and myristic acids,[2] while Thudichum's isomer of stearic acid has gained in probability since Kunz-Krause and Massute[3] have actually obtained such an acid from Indian cantharides, probably isomeric with stearic acid: $(C_4H_9)_2.CH(CH_2)_3.CH.CH_3.CH_2CHCH_3.COOH$.

All these findings indicate a great variety and complexity of the brain lipoids. This seems to apply to other tissues as well.[4] Moreover the lipoids seem to differ in different tissues so that specific tissue differences may perhaps in great measure be due to specific lipoids.

The specific nature of many of the lipoids is based not merely upon their isolation and chemical characterization but also upon experimental work in the field of hemolysis and immunity. Gottlieb and Lefmann,[5] and Lefmann,[6] have shown that the toxic substances of red blood corpuscles are probably lipoids because they are soluble in ether and in oil. Lefmann[7] has shown that the lipoids of the corpuscles of the same species of animal are not toxic whereas those of another species of animal may be very toxic. Bang and Forssman have offered similar evidence of the specific nature of the lipoids.[8] Noguchi[9] has shown that many hemolytic substances are merely soaps, while Faust and Tollquist[10] found that many unsaturated fatty acids are powerfully hemolytic. Neuberg[11] has shown that there is some sort of relation between hemolysis and lipolysis, for lipase always accompanies hemolysins. Noguchi[12] has also shown that the lipoids are concerned in bacteriocidal action. v. Liebermann[13] was able to use oleic acid as an immuno-body.

As one would expect from the discovery that the tissue lipoids occur in considerable variety, the unsaturated fatty acids are not confined to the brain. Leathes[1] and Hartley[2] as well as some of the investigators of tissue lipoids, already mentioned, have shown that fatty acids more unsaturated than oleic acid occur abundantly These are derived no doubt for the greater part from the lipoids but a part probably occur as glycerides.[3] The adipose tissues, however, contain none but the ordinary glycerides. Leathes[2] has therefore been led to the following view:

"It seems therefore that the fat is deposited in the connective tissues unchanged, changes subsequently taking place in it, with the result that it contains more of the unsaturated acid, before it is used in the organs in which it is broken up The unsaturated linkages become more numerous, presumably because it is at these points that the chains of carbon atoms are to break. If we could catch the process at a more advanced stage we should find that some of the unsaturated acids had disappeared, and the mean molecular weight of the acids had diminished. * * * * * We may expect that the fatty acids undergo oxidation step by step * * * * * that an unsaturated linkage is the first move towards this oxidation and probably the formation of a saturated oxyacid the second, the first of these preparatory changes takes place either in the organs where the oxidation is carried out or before it reaches them; but after it leaves the storage places, possibly in the liver."

That fat is transported from the depots to the liver is an old established fact (Lebedeff, Rosenfeld, Leick and Winckler). It may be supposed that this breaking up of the long chains results in such substances as caproic and acetic acids, of which it is known that the organism oxidizes them easily. Dakin's studies[4] upon the course of oxidation of such substances have thrown light upon this phase of intermediary metabolism. Von Furth[5] has described similar changes during the germination of seeds, a lowering of the iodine and acetyl values and the formation of acids of a lower molecular weight. For plants a very similar view has been expressed by Euler.[6] He assumes that hydroxyl groups appear primarily, followed secondarily by a breaking up of the molecule. The smaller cleavage fragments are completely burned, while the larger ones containing hydroxyl groups are utilized in the synthesis of carbohydrate. This is strikingly similar to the opinion expressed by Rosenfeld that fats are completely oxidized in the animal economy only when they become involved in the carbohydrate metabolism.

Schöndorff[7] finds that under special conditions of feeding fat is excreted by dogs through the urine. S. Levites[8] finds that the sodium salts of stearic, palmitic, and oleic acid are absorbed more rapidly than the free acids, and that oleic acid is absorbed more rapidly than palmitic and the latter more rapidly than stearic acid. Von Fürth and D. Schutz[9] obtained the opposite result, for they found sodium oleate and stearate less well absorbed than oleic acid or olive oil.

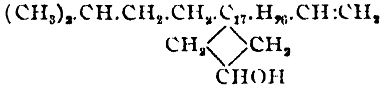
The study of the lipoids could hardly fail to stimulate the investigation of cholesterol which so often accompanies them. It has been shown that in plants a large number of different cholesterol occur.[1] The constitution has been investigated by Diels and Abderhalden,[2] by Diels,[3] by Mauthner[4] and by Windaus.[5] The results so far attained may be summed up in the following formula:



$$\begin{array}{c}(CH_3)_2.CH.CH_2.CH_2.C_{17}.H_{26}.CH:CH_2 \\ CH_2\langle\rangle CH_2 \\ CHOH\end{array}$$

From the behavior of cholesterol to ozone Molinari and Fenaroli[6] and Dorée[7] conclude that it contains a second double bond. It is interesting to note that cholesterol contains a five carbon ring which was known only in plants. The theory has been advanced that it is the source of these ring compounds in certain mineral oils. By the researches of C. Engler,[8] M. Rakusin[9] and J. Marcussohn[10] it has been shown that mineral oils owe their optical activity to cholesterol derivatives. C. Neuberg[11] objects to this view. Marcussohn believes these cholesterol compounds to be derived from marine animals, while Walden[12] ascribes them to the sitostearins of plants. Lewkowitsch[13] obtained by distillation of optically active glycerides (Chaulmugra oil) with zinc dust, optically active hydro carbons. In this case the optical activity is not dependent upon cholesterol but upon the configuration of the fatty acids. Neuberg, because of the rarity of such material, slights the experiments.[14]

Our knowledge of the physiological rôle of cholesterol has been increased by Dorée and Gardner, who found it to be a constituent of the cell membrane of the red blood corpuscles. In the bile it is derived from the membranes of destroyed corpuscles. It is to a great extent reabsorbed and used to help in the formation of new cell membranes.[15] It is supposed to be involved in hemolysis, being leached out, with lipoids, by such hemolytic agents as ether, etc., or combining with others such as saponins.[16] The addition of cholesterol often inhibits hemolysis. For hemoly-

sis by saponin Willstätter has found an explanation.[1] He found that when cholesterol in alcoholic solution is treated with digitonin, a typical saponin, a compound is formed which is insoluble in alcohol and can not be decomposed by extraction with ether. It no longer hemolyzes. Sitostearin, stigmastearin, koprostearin and dihydrocholesterol yield similar insoluble crystalline compounds. Cholesteryl esters, which do not hemolyze, do not combine with saponins.

This study of the lipoids has been accompanied by a study of the fat-splitting enzymes. The latter was especially stimulated by the possibility of using these enzymes commercially. Hoyer[2] studied the lipase of the castor bean, as did Taylor.[3] Mastbaum[4] found that of the cola nut, of maize, chestnut, and nutmeg, different from those previously studied. Dietz[5] found that pancreatic lipase not merely saponifies esters, but also synthesizes them, confirmation of older work of Kastle and Loevenhart. The enzyme reaction increases with the concentration, the equilibrium being independent of the latter. It is different from the equilibrium attainable with hydrogen ions, but why is not clear. Interesting is the study made by Dakin[6] of the action of lipase upon the antipodes of asymmetric acid esters. He found that while both esters were saponified, one form was saponified very much more rapidly than its antipode. A still more interesting observation is that of Bredig and Fajans,[7] who found that nicotine used as a catalyzer saponifies *d*-camphoric acid faster than the *l*-acid. We have here relations quite analogous to those of enzyme action, and light is therefore thrown on the "specific" action of enzymes. Not merely asymmetric hydrolysis, but asymmetric enzyme synthesis has been studied. A most interesting asymmetric enzyme synthesis has been discovered by Rosenthaler[8] with emulsin. In emulsin, which is a mixture of enzymes, there is one that accelerates greatly the condensation of benzaldehyde and prussic acid to mandelic nitrile, $C_6H_5CH(OH)CN$, and at the same time causes the radicals tied to the asymmetric carbon atom to arrange themselves in a definite way. This corresponds to *d*-mandelic acid, for on saponification of the nitrile formed, the latter acid with characteristic optical rotation is obtained. In an analogous way most of the aliphatic and aromatic aldehydes in the presence of emulsin combine with prussic acid to form optically active nitriles, while all hydroxyaldehydes and ketones behave differently. Another enzyme has been discovered in yeast. Harden and Young[9] and L. Ivanov[10] showed that in alcoholic fermentation with yeast juice free from yeast cells phosphates are converted into organic phosphorus compounds. Ivanov[11] believes them to be probably phosphoric acid derivatives of a triose, or of dihydroxyacetone, or methylglyoxal. Young[1] believes that they are probably esters of a hexose. He bases his view upon analytical data, cryoscopic determinations, and upon the fact that on saponification they yield fructose in all cases whether formed from phosphate with glucose, or with mannose, or with fructose. This synthesis takes place even when there is no fermentation provided the fermentation products be present. We have here presumably an enzymotic synthesis which perhaps explains the favorable influence of phosphates upon zymase fermentation. The other enzymes of yeast have also received much attention.[2]

Rennin (chymosin) and pepsin have also been actively studied. Taylor[3] found that in pyloric cancer the gastric juice has lost its rennin action, though retaining its peptic activity. He therefore concludes that rennin and pepsin are different enzymes. Hammarsten takes a similar view because treatment with weak hydrochloric acid under certain conditions yields a proteolytic but not a coagulating preparation.[4] Petry[5] thinks the proteolytic power of casein due to a new enzyme specific for casein. Van Herwerden agrees with him except that she does not accept the specific nature of the enzyme.[6] Sawjalow[7] and Gewin[8] also think coagulation is a step in the beginning of casein digestion. Van Damm[9] shows on the other hand that chymosin is a proteolytic enzyme and narrows Sawjalow's view down by showing the digestion is due to chymosin itself. He does not agree with Petry, and his evidence points to the identity of casein and pepsin.

The work upon oxidizing ferments has been very great. The whole question is in flux and much of the work is uncritical, due to the unreliability of most oxidase reactions and lack of quantitative methods. Such methods have been offered by v. Czilhary and v. Fürth[10] and by Wichern.[11] Much light is being thrown on this difficult field by the application of work on auto-oxidation.[12] Finally the laccase of *Medicago sativa* has been obtained pure by Euler and Bolin[13] and shown to consist of a mixture of the calcium salts of hydroxy acids, glycolic, glyoxylic, mesoxalic, citric, and malic. The possible significance of such bodies as the first three in respiration is obvious.

Indirectly oxidizing enzymes have also been studied in connection with the purine metabolism. It has been shown by Jones and his collaborators[14] and by Schittenhelm and his collaborators[1] that the various animal organisms contain a variety of enzymes which deamidize and oxidize purines. These authors do not agree upon the distribution and mode of action of these enzymes. Jones holds the view that five distinct enzymes are concerned in these processes: Nuclease, adenase, guanase, xanthooxydase, and uricolase.[2] Nuclease hydrolyzes nucleic acid, forming guanine and adenine; guanase and adenase remove the amino group from these two purines forming xanthine and hypoxanthine; xanthooxydase oxidizes hypoxanthine to xanthine and uric acid. Schittenhelm,[3] and Batelli and Stern, and others have studied the oxidation of uric acid. Wiechowski[4] and Austin[5] deny the force of the evidence for the existence of uric acid enzyme.

An increase in our knowledge of the constitution of nucleic acid has accompanied these advances in our knowledge of the nuclein enzymes. Levene and Jacobs[6] have shown that the pentose of inosinic, guanylic, and yeast nucleic acids is *d*-ribose, at the same time perhaps one of the most important recent contributions to the biochemistry of the carbohydrates. It is the first time this carbohydrate has been found in nature. By partial hydrolysis these authors have thrown much light on the constitution of nucleic acids generally. They believe that nucleic acids are of two types: (*a*) Simple ones, which they term nucleotides, consisting of phosphoric acid, carbohydrate and base (inosinic and guanylic acid); and, (*b*) complex ones (zoo- and phytonucleic acids), which are composed of a number of nucleotides, and which they therefore term polynucleotides. By methods of hydrolysis nucleotides yield two different types of complexes: (*a*) those that consist only of carbohydrate phosphoric acid; (*b*) those that consist only of the basic portion and the carbohydrate which they term nucleosides. Of the former they have prepared *d*-ribose-phosphoric acid from inosinic acid.[7] Of the nucleosides Haiser and Wenzel[8] discovered inosite in meat extract; Levene and Jacobs prepared guanosin from guanylic and yeast nucleic acids, and adenosin from yeast nucleic acid.[9]

Various pigments have been studied, more especially hematin and chlorophyl. Kuster[10] has continued his contributions to the constitution of hematin and bilirubin. The latter exists in several modifications differing in their solubility in chloroform. Qualitatively bilirubin and hematin yield the same oxidation products. Advance in the chemistry of chlorophyl is hampered by confusion in the nomenclature, as is well brought out in a discussion between Marchlewski and Willstätter.[11] The former

Under the same conditions xanthophyl would be more equally divided between the two solvents. Xanthophyl is $C_{40}H_{56}O_2$. Like carotin, it is strongly unsaturated, and absorbs oxygen from the air at ordinary temperatures.

The physiological significance of carotin and xanthophyl remains in doubt. Carotin may act as a carrier of oxygen. Xanthophyl, however, is not passed over in the spontaneous oxidation of carotin in the air, as is shown by the fact that xanthophyl will absorb 36.5 per cent. of its weight of oxygen, but carotin only 34.2 per cent.

V. Willstätter and Pfannenstiel[1] have investigated the remarkable series of transformations which take place on heating chlorophyllin with alcoholic potash. The first change occurs at the temperature of the water bath, in the assumption by the green solution of a strong fluorescence. At 140° the green substance breaks down with the formation of a crystalline product, which is blue with an intense red fluorescence. Finally at about 200° a deep red product is obtained. The products at each stage of the decomposition are mixtures of closely related compounds of similar color. All are magnesium compounds. Those of the first stage, green in color, are the chlorophyllins, those of the second stage, blue, glaucophyllins, and those of the third stage, red, rhodophyllins. One of the latter was prepared for investigation by heating chlorophyllin and potassium hydroxide in a silver beaker in an autoclave. Only one compound was thrown down when the reaction mixture was treated with water. Other related compounds remained in solution. The precipitate was purified by solution in ether and extraction with very dilute ammonia. It was found that the reaction between chlorophyllin and potassium hydroxide could not be carried on in sealed tubes of Jena glass because of the replacement of magnesium by zinc, derived from the glass. An identical rhodophyllin was prepared from *Chlorophyceae*, *Musci*, *Filices*, *Equisetum*, *Gramineae*, *Urticaceae* and *Platanus*, from which it was concluded that magnesium is an essential constituent of the chlorophyl of all plants. The formula which accords best with the analyses of samples of rhodophyllin prepared by various methods is $C_{33}H_{34}O_4N_4Mg$, but the data are hardly exact enough to exclude from consideration the formulas $C_{33}H_{36}O_4N_4Mg$, $C_{32}H_{34}O_4N_4Mg$, and $C_{34}H_{36}O_4N_4Mg$. In any case the compound is strikingly similar to hematin. By the action of acids, the magnesium atom is split from rhodophyllin with formation of a difficultly soluble crystalline derivative of red color, which accords in composition with the mesoporphyrin of Nencki and Zaleski, but is not identical with it. The authors give it the name alloporphyrin, and consider that it is derived from rhodophyllin by the substitution for magnesium (which is probably linked to N) of two hydrogen atoms. The metallic atom is considered to be in complex combination with basic groups of the molecule, in order to account for such color phenomena in the chlorophyl and hemin groups as are conditioned by the entrance of a metal into the compound.

VI. In a paper by Willstätter and Benz[2] the work of Borodin and of Monteverde on crystallized chlorophyl is reviewed and greatly amplified. The work of these students has heretofore hardly received due attention from chemists. The technique of Borodin has been improved so that yields of 2 grams of crystallized chlorophyl per kilogram of dry leaves have been obtained. The process, in essentials, consists of extraction with alcohol, transfer of the chlorophyl to ether, removal of emulsifying substances by shaking with talc, and of other impurities by shaking with water, and, finally, concentration on the water bath to the point of crystallization. The crystals were washed with small quantities of ether, to remove mother liquor, and then recrystallized from ether. The compound thus obtained would seem, from its spectrum, color, and indifference to dilute acids and alkalies to be an unaltered chlorophyl. It is by no means identical, however, with the greater part of the chlorophyl of even the plants from which it is obtained in greatest quantity, for it yields no phytol on hydrolysis, as does ordinary amorphous chlorophyl. It seems that all plants contain amorphous chlorophyl, but only certain ones (190 species out of 776 examined by Borodin) contain, in addition, crystalline chlorophyl. This would explain the varying yields of phytol from different samples of chlorophyl, and also the variation in composition of phaeophytin from different plants, for the compound from crystalline chlorophyl which is analogous to phaeophytin, namely phaeophorbin, probably often occurs as an impurity of phaeophytin when this substance is prepared from the total chlorophyl of plants which contain crystalline chlorophyl.

---

[1] *Ann.*, 358 205–65 (1908).

[2] *Ibid.*, 358, 267–87 (1908).

Crystalline chlorophyl prepared from *Galeopsis* gave 5.64 per cent. of ash-- pure magnesium oxide. On a basis of one atom of magnesium to the molecule, this would correspond to a molecular weight of 716, and the formula $C_{38}H_{42}N_4Mg$. As in the case of amorphous chlorophyl, the magnesium atom is readily split off by dilute acids.

A substance for which as for cholesterol no physiological function was known, inosite, has been the subject of investigation. W. Windisch[1] has shown that a mother substance for it is phytin, confirming older observations of Jordan, Hart and Patten[2] while Mayer[3] has shown that when inosite is fed in large doses to rabbits fermentation lactic acid appears in the urine. Concerning lactic acid we have learned much through Fletcher and Hopkins.[4] They have shown that our methods for its determination in muscle are very unreliable. Though they have thrown much light upon the genesis of this acid they have not endeavored to discover its precursors in the animal body. Herzog and Hörth[5] have studied the stereochemistry of lactic acid fermentation; and have found that different bacteria acting upon different sugars usually form an acid, which is a mixture of active and inactive acid.

There have been other advances in the biochemistry of lactic acid, particularly in regard to its rôle in the intermediary metabolism in relation to both the carbohydrates and the amino acids. While these researches ought, strictly speaking, to be included in this review, to do so would lead us into the field of intermediary metabolism in which there have been some notable advances. To treat them adequately would require more

space than is at my disposal, so that a review of these advances as well as those very important ones resulting from the application of physical chemistry to biology must be postponed to some future date, at which time the many errors of omission of which I am conscious may, I hope, be amended.

WASHINGTON, D C

NEW BOOKS.

Einführung in die Chemie. Ein Lehrbuch für höhere Lehranstalten und zum Selbstunterricht. By WILHELM OSTWALD, Stuttgart, 1910: Franckh'sche Verlagshandlung. pp. 238; 74 illustrations in the text. Cloth, 3 Marks net.

In this textbook it is the main object of Professor Ostwald to educate the student to "chemical thinking," to supply a basis for chemical understanding and to deepen the logical analysis of the chemical phenomena. Contrary to the methods pursued in most other textbooks, Professor Ostwald prefers to give only the data absolutely necessary for the understanding of the scientific consequences and to describe only the phenomena absolutely essential for grasping the real educational value of chemistry.

This is quite a new departure, since in most of the textbooks such a lot of material is presented, that the students get the impression that by learning the contents of the respective book he will know all about chemistry. Ostwald's book, on the contrary, incites to further thinking and impresses the student with what may be called scientific modesty. The first five chapters contain a discussion of matter, mixtures, physical transformations, solutions and chemical processes. Chapters 6 to 13 describe the metallic and non-metallic elements and compounds in a clear and concise, *i. e.*, really Ostwaldian manner. The book will prove as useful to the teacher as to the student.

OSKAR NAGEL.

Introduction to Physical Chemistry. By HARRY C. JONES, Professor of Physical Chemistry in the Johns Hopkins University. New York: The Macmillan Co 1910. xv + 279 pp. Price, $1.60 net.

So far as we know, this is the most recent work from Prof. Jones' pen. Using 'recent' as he uses it, however, we could not feel secure in this statement. "Quite recently" on p. 47 refers to 1895, and on p. 113 to 1899. The epoch of writing may, however, perhaps be fixed from internal evidence for (p. 136) 'Berthelot's experimental work has continued up to the present' and "van't Hoff's paper on the subject of solid solutions appeared about eleven years ago." The purpose of the book is sufficiently obvious from the title. Symptoms of adaptations from the author's larger works appear at times rather prominently. Thus we find, on p. 67, two liquids becoming miscible in all proportions, "as we have just seen." We have not, however, seen it in the present volume.

Again, we are told, on p. 26, that the author will call the temperature coefficient of gases "B." Having mentally agreed to this and assimilated the significance of "B," we read on in expectation. "B," however, fails to put in any further appearance. But we must not be too disappointed, for this is an optimistic book We find the author taking a characteristically optimistic view of the agreement of results "found" with those calculated by theory on p. 61. Here we notice divergencies of 10 per cent. and more in the square of a quantity calculated from measurements of absolute boiling point and of densities at 0°, both of which quantities are customarily measured with concordance of well within half a per cent. by different observers. The agreement is, nevertheless, stated to be "almost within the limits of experimental error." Optimism is a good fault, and is well in keeping with the vigor and freshness that characterizes much of the exposition. No book is without its *corrigenda,* and the following are among points that might perhaps receive attention. For the atomic weight of radium read 226 4, not 225 (p. 11), and 226 7, not 227.7 (p. 151). These are misquoted from the sources given. This element suffers again in being omitted from the table of the periodic law (p. 13). Mass is "the only property of substances that remains unchanged in chemical reaction" (p. 1). Surely orthophosphoric acid can be titrated with phenolphthalein as indicator (p. 112). As far as one can gather from p. 129, the equivalent concentration of hydrogen ion in pure water at 18° is 0 68. On p. 196, water is the strongest dissociant known; but, on p. 194, water stood second to liquid hydrocyanic acid. "Compounds of uranium when exposed to light" emit radiation—is true but perhaps misleading, while "this property is possessed by metallic uranium to from three to four times the extent that it is manifested by the salts" seems to miss the main point of interest. "The definition of an atom as an individual particle of matter shows that fractions of atoms cannot exist" (p. 8). "When barium sulphate and sodium carbonate were pressed together and the pressure removed, the transformation continued, and in seven days amounted to from 73 to 80 per cent." The "73 to 80" is circumstantial, and adds realism; but how thick were the layers? Socratic method is antiquated and slow, else many a beginner might ask ingenuously, "What is intrinsic energy?" (p. 133). Nowadays, one must hurry on and catch the meaning subconsciously as the discussion proceeds.

It is probably difficult for the author to view his subject continuously from the introductory level; and, in writing, it must be tiresome to recall the precise state of ignorance of his reader. Perhaps for this reason we find, for example, Ostwald's dilution law, the isohydric principle, etc., discussed before chemical equilibrium; the theory of indicators before hydrolytic dissociation, etc. There are no forward references. The beginner will doubtless be willing to admit his own obtuseness, but he will be disconcerted.

The book is very free from typographical errors and is, of course, excellently produced. There are 31 efficient diagrams and figures in the text. Though the pedagogy is a weak feature, the style has a refreshing air of activity and modernness, while the matter selected is generally accurate and always interesting. We feel certain, however, that this is not yet the ideal "Introduction to Physical Chemistry." Let the Quest continue. ALAN W. C. MENZIES.

Analyse der Silikat– und Karbonat Gesteine. Von W. F. HILLEBRAND. Deutsche Ausgabe von ERNST WILKE-DORFURT. Leipzig: von Wilhelm Engelmann, 1910.

This volume in its German dress contains numerous additions made by its author to previous editions. The fact that German students have recognized its merits and want it in their own language reflects great honor upon its author. Years ago, within the knowledge of some of us, the Fatherland was the seat of most thorough training in mineral analysis. To-day, however, as evidenced by the rich fund of reliable information in this special publication and in other similar publications, America may justly lay claim to this position.

The careful perusal of its pages proved most refreshing to the reviewer, and if he may be allowed a word of advice to students of chemistry, it would be: Study the contents of this book; put to test the methods and experiences therein described. A vast fund of new knowledge will be the reward, a deeper respect for analytical methods and their significance and value will be engendered, while the feeling of contempt so frequently manifested for the work of the mineral analyst will absolutely disappear, and a wider and wholesomer view of the whole field of chemical science will result. Teachers of more advanced students in analysis will realize the greatest pleasure and profit in the consideration of the many topics of this volume in their seminars. EDGAR F. SMITH.

Das Radium und die Farben. PROFESSOR DR. C. DÖLTER, Vorstand des Mineralogischen Institutes der Universität Wien. Verlag von Theodor Steinkopf, Dresden. 1910. pp. 133. Preis, geb. M. 5.

The discovery of radium and a recognition of the complex influences of its several forms of energy have aroused unusual interest for several reasons, but mainly, because, first, radium salts, in their decomposition produce canal and cathode (magneto- or electro-magneto-deflectable) and gamma (Röntgen) rays, exert specific, analytic and synthetic influences, physical, chemical and physiological, which might in a large sense be grouped under the head of chemical; second, when all that is positively known of these influences is applied to the world's history, petrographical and geological, a revision of previous ideas of changes that have taken place and calculations as to the age of the earth have become necessary.

The author has had unusual facilities in Vienna for the study of the many and varied changes produced through the influence of radioactivity. He has taken advantage of them. The book presents the results of his elaborate investigation. It is filled with meat and cannot fail to be of interest to mineralogists, geologists and those chemists who desire further information as to the influence of these complex rays upon matter. It has a good index. CHAS. BASKERVILLE.

The Simple Carbohydrates and the Glucosides. By E. FRANKLAND ARMSTRONG. (Monographs on Biochemistry Series) 112 pages. Longmans, Green & Company. Price, $1.20 net.

This short monograph by Dr. Armstrong, an English investigator of the first rank in carbohydrate chemistry, is a well-written summary of the advances of the last fifteen years in the chemistry of the sugars. Naturally it is impossible to describe these advances in a manner that is satisfactory to an inquiring reader in the space of 112 pages, and it is to be hoped that later editions will be more inclusive. But the monograph is a good beginning and should be widely read by chemists and biologists. To understand the chemical or biological actions of the sugars it is essential to have a clear knowledge of their mutarotation and Dr. Armstrong's book furnishes a good description of this phenomenon. A valuable eighteen-page bibliography is appended. On page 47 the discovery of β-lactose, which was made by E. O Erdmann, is credited to C. Tanret. The discovery that the mutarotation of glucose is a balanced reaction is ascribed on page 8 to Lowry; the reviewer believes that he made the same discovery in the case of lactose in the year preceding Lowry's publication, and that his priority in the discovery of the cause of the mutarotation reaction has been recognized in such a standard work as Nernst's "Theoretische Chemie." Dr. Lowry and he worked independently, the former on glucose, the latter on lactose. C. S. HUDSON.

A Course in Inorganic Chemistry for Colleges. BY LYMAN C. NEWELL, PH.D (Johns Hopkins), Professor of Chemistry, Boston University. Published by D C. Heath and Company, Boston. pp. x + 594. Price, $2 00

This is practically a new and enlarged edition of the author's well-known Descriptive Chemistry. A chapter on Solutions has been added and the chapters on Silicon-Boron and Chromium-Manganese have been enlarged and divided into two separate chapters. While the main portions of the text are identical with the Descriptive Chemistry, yet considerable new material has been added and the subject brought up to date. In a few cases the order of the chapters has been changed. The questions at the end of the chapters have been omitted, but the lists of problems remain. The book is conservatively modern in spirit and is deserving the same cordial recognition given the author's former work.

WILLIAM MCPHERSON.

Outline of Bacteriology (Technical and Agricultural). BY DAVID ELLIS. Longmans, Green & Co , 1909 pp. xii, 262 Price, $2 50

Dr. Ellis, of the Glasgow Technical College, has attempted to write "an introduction to bacteriology in all its branches, though more attention has been bestowed on that aspect of the subject which is of most interest to students of technical and agricultural bacteriology." The plan of his book is an excellent one. There is great need for text-books of bacteriology which shall develop the broader biological facts of the science, without undue emphasis on the details of its application to medicine. It requires, however, an unusual grasp of the subject, a strong sense of proportion, and some literary skill to produce a book of this type. Fischer in the Vorlesungen uber Bacterien has succeeded in doing it: but his admirable volume stands practically alone. The present author gives less of a philosophical treatment of fundamental questions, than a series of more or less independent facts such as make up the bulk of so many books on bacteriology and hygiene. For example in the chapter on sterilization, thirty-three different chemical disinfectants are discussed in detail, including such substances as nitrogen dioxide, butyric acid, camphor and coffee infusion. Dr. Ellis gives his well known views about motility and spore formation among the cocci as established facts without pointing out that they are still in the controversial stage. Here and there are statements of a somewhat superficial character which are likely to prove misleading. The industrial and agricultural chapters, modeled pretty closely after Lafar, are freest from such defects, and the medical and sanitary sections are most prone to them. Thus it is stated that the same species of bacillus causes tuberculosis in man and in cattle (p. 120), and that infection in tuberculosis takes place almost exclusively through the air (121). The colon bacillus is introduced as follows: "There is great similarity between *B. typhosus and Bacillus coli communis*, an organism which is very common in sewage, and which is strongly suspected of being the cause of epidemic diarrhoea, though positive proof is still wanting." Altogether the book is not a sufficiently scholarly work to form a very valuable contribution to the subject. C.-E. A. WINSLOW.

HALIDES OF TANTALUM.[1]

BY WALTER K. VAN HAAGEN.

Received April 4, 1910.

The chloride alone of all the possible halides of tantalum has received more than passing attention. A bromide has been recorded but the iodide is absent from our literature. H. Rose[2] claimed to have obtained the bromide by strongly igniting a mixture of tantalic oxide and carbon in a current of carbon dioxide laden with bromine vapor. He failed to give any analytical results. He surmised that his product was the bromide. Moissan believed it was produced upon heating tantalum metal in a stream of bromine vapor.

With pure materials the conditions essential for the satisfactory preparation of tantalum pentabromide may be briefly summarized:

1. Tantalic oxide, previously strongly ignited, should be intimately mixed with an excess of pure carbon, an equal weight of the latter being a convenient and quite sufficient amount. Starch carbon answers well but it usually leaves an appreciable ash, hence pure sugar carbon is preferable. The excess of carbon indicated makes the mass sufficiently permeable to the bromine.

2. Air should be completely expelled. Raise the charge to a full red heat in a current of carbon dioxide to remove the last traces of moisture.

3. Phosphorus pentoxide is essential as the final drying agent for the carbon dioxide.

4. A high temperature must be maintained during the passage of the bromine, otherwise nearly all of it will escape unchanged.

---

[1] An abstract from the author's doctoral thesis (190).

[2] *Pogg. Ann.*, 99, 87 (1856).

5. The resulting pentabromide should be fused from time to time in order that the combustion tube may not be obstructed.

It is easy to get a yield of about 70 per cent. of the theory.

The product from the above procedure was resublimed in an atmosphere of carbon dioxide. Upon analysis it showed:

				Theory.
Ta =	32.21	32.03	31.79	31.39
Br =	68.70	68.68	68.38	68.61

Tantalum pentabromide consists of yellow, elongated lamellae, curving or clinging to the tube in beautiful arborescent forms resembling frost flowers. They fuse easily to a transparent, ruby colored liquid. Their color is suggestive of that of potassium bichromate. They may be sublimed without melting. The vapor of the bromide is yellow in color, somewhat resembling that of chlorine. The bromide melts at about 240° and begins to boil at 320°. It fumes strongly in the air. It dissolves rapidly in absolute methyl or ethyl alcohol, forming at first an amber-yellow colored liquid which soon becomes colorless. Usually, the heat generated causes the alcohol to boil. These reactions certainly point to tantalic esters. Anhydrous ethyl bromide is an interesting solvent for tantalum pentabromide. When the latter is brought into this liquid heat is evolved and a reddish colored solution results. If the latter be cooled in water or evaporated in a vacuum desiccator golden yellow colored crystals separate. The solution fumes strongly in the air.

Tantalum pentabromide may be sublimed in an atmosphere of hydrogen. This is possible at a temperature just sufficient for the sublimation. At more elevated temperatures a partial reduction to the metallic state occurs. If a lower bromide of tantalum should exist such a compound would not be unlikely to appear at some stage during the reduction of the pentabromide in hydrogen. At first there seemed no evidence of this. At times, however, the sublimate appeared to be different. Indeed, it had been noticed that toward the posterior end of the tube, *i. e.*, beyond the metallic deposit, there was a slight greenish, partly almost black film. It dissolved in water with an intense green color, and in methyl and ethyl alcohol with the same color. Its analysis indicated a tantalum tribromide, but Chapin, in this Laboratory, has since demonstrated that it is not this, but that it is in reality a bromo-tantalum bromide $(Ta_6Br_{12})Br_2$.[1]

An oxybromide of tantalum was not observed.

Efforts were made both by Rose[2] and by Moissan[3] to obtain an iodide of tantalum but without avail. So the query presented itself: is it not possible to transpose tantalum bromide by means of a suitable iodide? Silver iodide suggested itself for this purpose. Accordingly tantalum pentabromide was distilled through a column of granular, well-dried silver iodide in a current of carbon dioxide. A brown sublimate resulted. It contained considerable free iodine, which was carefully expelled and the residue analyzed. This analysis indicated a pentabromide with unmistakable evidences of combined iodine. How could there be free iodine unless there had been a reduction of the bromide?

---

[1] W. H. Chapin, THIS JOURNAL, 32, 323.

[2] *Pogg. Ann.*, 99, 593 (1856).

[3] *Compt. Rend.*, 134, 211–215.

Finally it was found that the potassium iodide used in the preparation of the silver iodide contained some iodate. Most likely then the reaction had proceeded as follows:

$$7TaBr_5 + 5AgIO_3 = TaI_5 + 3Ta_2O_5 + 5AgBr + 15Br_2.$$

The liberated bromine set free iodine from the silver iodide and probably from the tantalum iodide, allowing only a small amount of the latter to escape, while by far the greater portion of the bromide distilled over unchanged. This view is further supported by the fact that iodine separates when tantalum pentabromide is distilled through a layer of potassium iodate.

The next thought was to try hydrogen iodide. Accordingly tantalum pentabromide was slowly distilled in a steady stream of anhydrous hydriodic acid gas. Soon the reddish color of the bromide changed to brown, while the escape of hydrobromic acid, together with the excess of the hydriodic acid, could be proved at the exit of the tube. Further an analysis of the dark brown product showed that only one-third of the bromide had been converted into an iodide. Therefore the experiment was repeated, about three grams of the pentabromide being distilled as slowly as possible in a brisk current of hydrogen iodide for about four hours. The product was brownish black in color and showed much iodine. Its tantalum content was found to be 22.98 instead of 22.37 per cent. as required by TaI_5. The remainder of the preparation was subjected to another distillation in hydrogen iodide and analyzed with these results:

	Per cent.	Per cent.
Ta	22.62	22.51
I	77.27	77.35

The required percentage of iodine for the pentaiodide is 77.63. These results prove the formation of an iodide, TaI_5. It sublimes in dark, nearly black lamellae, bearing a remote resemblance to iodine crystals. It fuses to a dark brown liquid. Its vapor is like that of bromine. It may be distilled in a current of carbon dioxide without the separation of iodine. It resembles the bromide in its deportment toward moist air and water. An intermediate oxyiodide was never observed.

THE POTENTIAL OF THE THALLIUM ELECTRODE.

BY GILBERT N. LEWIS AND CARL L. VON ENDE.

Received March 25, 1910.

The first determination of the electrode potential of thallium was made by Neumann[1] who obtained the following values:

			Volt.
Tl, Tl_2SO_4	(saturated),	N. E.;[2]	$E = +0.674$
Tl, $TlNO_3$	(saturated),	N. E.;	$E = +0.671$
Tl, TlCl	(saturated),	N. E.;	$E = +0.711$
Tl, TlA	(0.1 N),	N. E.;	$E = +0.677$
Tl, TlA	(0.02N),	N. E.;	$E = +0.705$
Tl, TlA	(0.01N),	N. E.;	$E = +0.715$

The last three values are averages obtained from the study of 23 thallous salts, chiefly of organic acids, at the three concentrations given. Neumann believed his results to be entirely reproducible. In fact he found the potential of thallium in the twenty-three salts at hundredth-normal concentration to be the same within one millivolt. This agreement must have been purely accidental for we shall see that all of Neumann's measurements of the thallium potential were attended by a very large error of entirely fortuitous character.

The doubtful character of Neumann's determinations is apparent when the above values of the thallium potentials are plotted against the logarithms of the ion concentrations, as in Fig. 1. The continuous straight line shows the way the potential would change with the ion concentration according to the Nernst equation; the points enclosed in circles show the values obtained by Neumann. These obviously neither follow the

[2] N. E. stands for normal electrode. A positive electromotive force, E, indicates always that the current tends to pass in the cell from left to right.

theoretical curve nor show any great regularity in their deviation therefrom.

The dependence of the thallium potential upon the concentration of thallous ion has ben recently studied by Abegg and Spencer[1] with various concentrations of thallous nitrate, chloride, sulphate and hydroxide. Their results for the potentials in different concentrations of thallous chloride are reproduced in Fig. 2, where the continuous line again represents the theoretical change of potential with the concentration. The authors conclude that the Nernst formula is not even approximately true for the thallium electrode. This conclusion is also reached by Shukow [2]

In all cases studied the potential changes less rapidly with the concentration than theory requires, and in all cases the deviations are greater the more dilute the solutions. This could readily be explained by assuming that the thallium electrode is oxidized by the oxygen contained in the solution, thus increasing the concentration of thallous ion next the electrode. The percentage change of concentration thus produced would obviously be greater in the more dilute solutions. This possibility, however, was considered both by Zhukov and by Abegg and Spencer, and in both cases precautions were taken which seemed adequate to preclude it.

Any other explanation must depend upon the assumption of some abnormality in thallous ion. In fact Denham[3] has claimed that metallic thallium in the presence of thallous ion forms sub-thallous ion. Kohlrausch and von Steinwehr[4] have suggested that a somewhat anomalous trend in the conductivity of thallous chloride indicates the tendency on the part of thallium to form complex ions. Finally we might surmise the formation of a double ion Tl_2^{++} analogous to the one which is supposed to exist in the case of univalent mercury. On account of these various possibilities it seemed desirable to investigate the subject more closely from the experimental side.

The Effect of Thallous Ion Concentration upon the Potential of Thallium.

The solutions used in this investigation were made from salts carefully purified by suitable recrystallizations, and from doubly distilled water. The metallic thallium employed came from two independent sources (Kahlbaum, Eimer and Amend) and both varieties proved to be identical in electromotive behavior. In determining the effect of the various solutions upon the potential, the kind of thallium electrode used was unimportant provided that it be constant and reproducible. A concentrated but

[1] *Z. anorg. Chem.*, 46, 406 (1905).

[3] *Proc. Chem. Soc.*, 24, 76 (1908).

[4] *Ber. Berlin. Akad.*, 1902, 581.

unsaturated thallium amalgam, prepared with doubly distilled mercury, proved most satisfactory. The amalgam used contained 20 per cent. thallium and was kept in a pipette provided with stopcocks, where it was protected from atmospheric moisture and could be withdrawn as needed. All measurements were made in a thermostat maintained at 25.00°.

The solutions were prepared by dissolving known weights of the dried salts, or from saturated solutions obtained by shaking the salt and water together in the thermostat for 24 hours. These solutions were introduced into electrode vessels of the ordinary "half-cell" type together with the 20 per cent. amalgam. These half cells could then be measured against one another or against a single one chosen arbitrarily. The one so chosen contained a saturated thallous chloride solution with an excess of the solid salt lying above the amalgam.

The first series of experiments was made with solutions of thallous chloride and nitrate. On account of the almost equal mobility of thallous ion and chloride ion the liquid potential between different solutions of thallous chloride may be entirely neglected. Between electrodes in chloride and nitrate of the same concentration a small difference was observed corresponding as nearly as could be observed to the calculated potential[1] between the liquids. It was found possible to eliminate this difference by interposing a normal potassium chloride solution between the two liquids, and this was done in the succeeding experiments.

The results of this series are given in Table I where the first column shows the salt used and its concentration (*S* denotes a saturated solution). The third column gives the potential between the electrode in question and the one in saturated thallous chloride. Each value is the mean of several determinations, which, in the concentrated solutions, were very concordant.

TABLE I.

	Volt.		Volt.
$TlNO_3$ 1/10 *N*	−0.0414	TlCl 1/200 *N*	+0.0240
$TlNO_3$ 1/30 *N*	−0.0175	$TlNO_3$ 1/200 *N*	+0.0228
$TlNO_3$ 1/40 *N*	−0.0112	TlCl 1/5 *S*	+0.0301
TlCl *S*	0.0	TlCl 1/400 *N*	+0.0356
TlCl 1/100 *N*	+0.0104	$TlNO_3$ 1/400 *N*	+0.0339
TlCl 1/2 *S*	+0.0144		

These values are plotted in Fig. 3 against the concentrations of thallous ion, the latter values being obtained with the aid of degrees of dissociation calculated from Kohlrausch's conductivity data. The solubility of thallous chloride at 25° is taken as 0.0161 *N*. This is the value obtained in perfect agreement both by Noyes[2] and by Kohlrausch.[3]

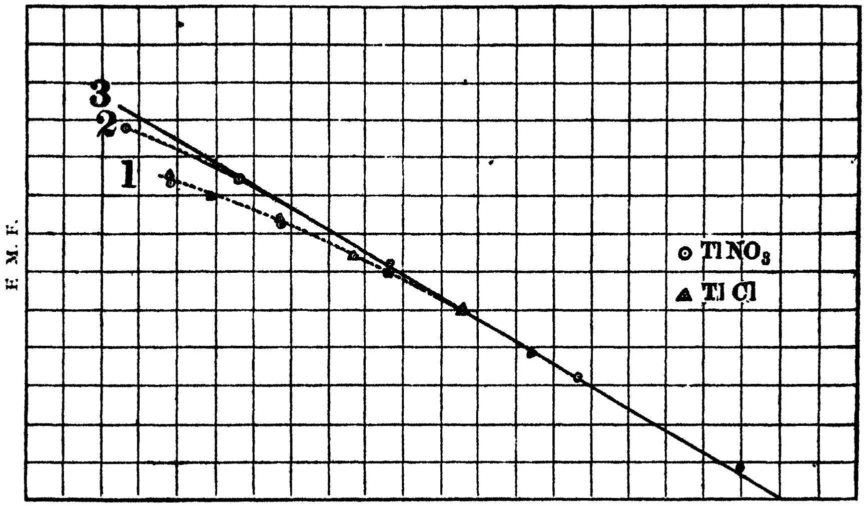
---

[1] See Lewis and Sargent, THIS JOURNAL, 31, 363 (1909).

[2] *Z. physik. Chem.*, 49, 296 (1904).

[3] *Ibid.*, 64, 149 (1908).

In the dilute solutions there is obviously an increasing divergence from the straight line (3) demanded by the Nernst equation. However, this divergence, although in the same direction, is so much smaller than that found by previous investigators, and the potentials measured were so much less certain in the dilute solutions than in the concentrated, that we were inclined to believe the apparently anomalous behavior of the dilute solutions to be due to some cause latent in the experimental method. This suspicion was confirmed when the solutions which had been used with the thallium electrodes were tested with phenolphthalein and found to be decidedly alkaline.



Log ion concentration

Fig. 3

This alkalinity must obviously be due to the oxidation of metallic thallium by dissolved oxygen. The small amount of thallous hydroxide thus produced is insufficient to produce an appreciable percentage increase in thallous ion concentration in the concentrated solutions, but evidently might be sufficient in the dilute solution to cause the low potentials observed. For this reason several dilute solutions were investigated further with two additional precautions. The first consisted in exhausting the solutions of air as far as possible,[1] the second in filling the electrode vessel first with solution and then introducing the amalgam through a capillary dipping below the surface of the solution. These changes resulted in an increase of 0.0008 volt in the potential of the electrode with saturated thallous chloride. The other new electrodes measured against this new thallous chloride electrode gave the values in Table II.

---

[1] It was found possible to exhaust a solution without appreciably changing its concentration, by boiling it for a minute or two under reduced pressure at a temperature of 25° to 30° C.

TABLE II.

	Volt.		Volt.
TlCl *S*	0	$TlNO_3$ 1/262 *N*	+0.0346
$TlNO_3$ 1/100 *N*	+0.0121	$TlNO_3$ 1/515 *N*	+0.0480

These data are shown also in Fig. 3, and are represented by the points lying on the second dotted curve (2). These points approach very close to the theoretical except at the highest dilution. Moreover, the solutions still gave a faint coloration with phenolphthalein, showing the presence of amounts of thallous hydroxide which, though very small, might affect the potential at high dilutions. Of the values thus far obtained those least likely to be affected by the oxidation of the electrode are undoubtedly those for the two most concentrated solutions, tenth- and thirtieth-normal $TlNO_3$, and the two most concentrated of the diluter solutions in which special precautions were taken, namely, saturated thallous chloride and hundredth-normal thallous nitrate. These values agree very closely with the Nernst formula and it seemed particularly desirable to obtain an equally reliable value for a more dilute solution, in order to test the formula over as wide a range as possible.

We had already observed that an electrode under saturated thallous chloride, with excess of solid thallous chloride, was more reproducible than one containing the same concentration of an unsaturated thallous salt. This was to be expected since a small amount of thallous ion accidentally added to saturated thallous chloride would be largely removed from the solution as solid thallous chloride. For this reason we decided to use for the most dilute solution a saturated solution of thallous bromide. This has a solubility at 25° of 0.00199 *N* according to the recent work of Kohlrausch,[1] whose measurements moreover agree perfectly with those of several other observers.

A saturated solution of this salt and an excess of the solid were placed in a specially designed electrode receptacle through which very pure hydrogen could be passed continuously, so as to bubble through the solution. When this process had been continued long enough to insure the removal of all the oxygen from the solution and the gas above it, by turning a stopcock the thallium amalgam was allowed to enter through a fine capillary. The electrode thus prepared gave, against the saturated TlCl electrode, a very constant potential of +0.0521 volt and the solution after long standing in contact with the electrode gave no coloration with phenolphthalein. We may therefore consider this potential as reliable as the four mentioned above. We reproduce these five values in Table III, which gives the concentration, *C*, of the salt used, the degree of dissociation, α, as obtained from conductivity measurements, the ion concentration, *C'*, the potential, *E*, against the saturated thallous chloride electrode, and the values of *E* calculated from the Nernst equation. These data are also plotted in Fig. 4.

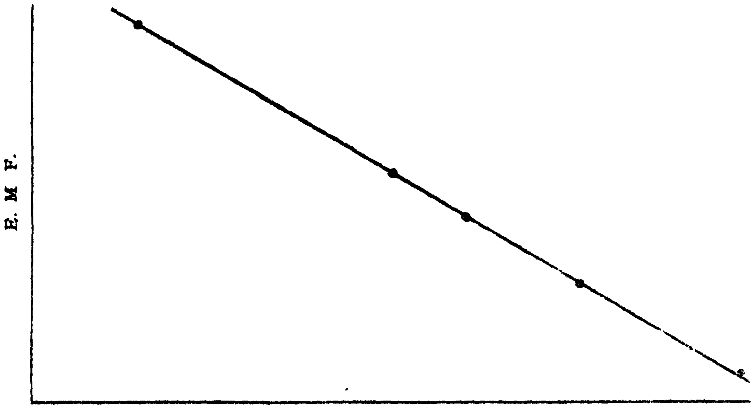
---

[1] *Z. physik. Chem.*, 64, 149 (1908).

TABLE III.

	C	α.	*C'*.	*E*.	*E* (calc.).
$TlNO_3$	0.100	0.79	0.0790	—0.0422	—0.0438
$TlNO_3$	0.0333	0.88	0.0293	—0 0183	—0.0182
$TlCl(S)$	0.0161	0.89	0.0143	0	(standard)
$TlNO_3$	0.0100	0.93	0.00930	+0.0113	+0.0113
$TlBr(S)$	0.00199	0.97	0.00193	+0.0513	+0.0516

The deviation of one and a half millivolts between the observed and calculated values for tenth-normal thallous nitrate is undoubtedly real, and not to be attributed to experimental error. Moreover such a real deviation from the Nernst equation in the direction found is to be expected in the case of a solution as concentrated as tenth-normal. There is much experimental evidence to show that if conductivity is taken as a measure of ion concentration, the ions (although much less abnormal in behavior than the undissociated substance) do not quite obey the laws of a perfect solution. The ratio of their activity[1] to their concentration, which should be constant, diminishes somewhat at the higher concentrations.[2]



Log. ion concentration.
Fig. 4.

The remaining values agree remarkably with the Nernst equation, the deviations being irregular, and amounting in no case to more than 0.0003 volt. This agreement, and the constancy of the potential when the solutions in the electrode vessels are stirred, we regard as strong evidence against the existence of the subthallous ion assumed by Denham.[3]

Instead then of finding any anomaly in the electromotive behavior of thallous ion, we may assert that the Nernst equation holds for the thallium electrode over a large range of concentration with greater accuracy than it has as yet been shown to do in the case of any other electrode.

---

[1] See Lewis, *Proc. Am. Acad.*, 43, 259 (1907); *Z. physik. Chem.*, 61, 129 (1907).

[2] In an article about to appear in THIS JOURNAL, Bray and Mackay point out an interesting case in which this rule is confirmed.

[3] *Loc. cit.*

The Thallium Electrode Potential.

In order to determine the absolute electrode potential of thallium, we must use an electrode of pure metallic thallium or some electrode that is its equivalent. It was shown by Kurnakov and Puschkin[1] that thallium and mercury form no solid compound above 15°. Sucheni[2] showed that mercury does not dissolve to any extent in solid thallium, and that a saturated solution of thallium in mercury therefore has the same potential as pure thallium. This fact, which we have also corroborated, enables us to use a paste of thallium and thallium amalgam in place of solid thallium, which like all solid metals gives an inconstant potential owing to uncontrollable surface variations.

A mixture of 55 parts thallium and 45 parts mercury was warmed until liquid in the electrode vessels. After cooling, the electrodes were rinsed with the solution to be used and the vessels then filled. After this rinsing, electrodes prepared without special precautions gave the same results as those prepared in the total absence of oxygen. The first experiments, with three electrodes of this type (in two of which the amalgams were made from samples of thallium of different origin) were made with saturated solutions of thallous chloride containing an excess of the solid chloride. In the first case no special precautions were taken, in the second the solution was freed from air by exhaustion, in the third by a stream of hydrogen. Against the normal electrode the electromotive forces were 0.7258, 0.7256, 0.7257, respectively. We may write, therefore,

$$\text{Tl, TlCl (sat.) N. E.; } E = 0.7257 \text{ volt.}$$

The ion concentration of thallium in the saturated chloride solution is 0.0143 N. From the Nernst equation,

$$\text{Tl, Tl}^+(N)\text{, Tl}^+(0.0143\ N)\text{, Tl; } E = 0.1087 \text{ volt.}$$

Adding these equations gives

$$\text{Tl, Tl}^+(N)\text{, N. E.; } E = \underline{0.6170 \text{ volt.}}$$

On account of the almost equal mobility of thallous and potassium ions, the liquid potential is here negligible. Therefore, the potential of the thallium electrode, when the normal electrode is taken as zero, is 0.6170 volt at 25°.[3]

We also investigated electrodes of saturated thallium amalgam under tenth-normal and normal potassium chloride saturated with thallous chloride. Electrodes of this type were used successfully by Sucheni and we find them, as was to be expected, much less affected by any oxidation of the electrode than the other types that have been used. The electrodes with tenth-normal potassium chloride gave against the normal electrode the following potentials in four experiments, the last one being made with a new potassium chloride solution prepared from salt of a different origin. (1) 0.7707, (2) 0.7704, (3) 0.7705, (4) 0.7708. The average is therefore,

---

[1] *Z. anorg. Chem.*, 30, 86 (1902).

[2] *Z. Elektrochemie*, 12, 726 (1906).

[3] As in other cases, this is not the potential against a real normal solution of thallous ion, but against a sort of hypothetical normal solution, between which and a dilute solution the Nernst formula would hold. This potential would in any case be more useful in calculation than that against the real normal solution, even if the latter value could be obtained.

$$\text{Tl, TlCl (solid), KCl } (1/10\,N),\text{ N. E.; } E = 0.7706 \text{ volt.}$$

From this value also it is possible to calculate the normal potential of thallium, although this calculation is less justifiable than the one above, since it assumes the validity of the laws of the perfect solution up to a higher concentration. The solubility product of TlCl is (0.0143),[2] and the concentration of Cl^- due to the potassium chloride may be taken as 0.085, allowing for the degree of dissociation, in the presence of thallous chloride; then, if x is the concentration of thallous ion, we obtain from the solubility-product rule,

$$(0.085 + x)\,x = (0.0143)^2.$$

Hence $x = 0.00234$ and the above equation for electromotive force may be written

$$\text{Tl, Tl}^+ (0.00234\,N),\text{ N. E.; } E = 0.7706 \text{ volt.}$$

From the Nernst formula,

$$\text{Tl, Tl}^+ (N),\text{ Tl}^+ (0.00234\,N),\text{ Tl; } E = -0.1555 \text{ volt.}$$

Hence,

$$\text{Tl, Tl}^+(N),\text{ N. E.; } E = 0.6151 \text{ volt.}$$

The difference of nearly two millivolts between this value and the one obtained above is not to be ascribed to experimental error, but was to have been predicted from the principle stated above, namely that when we calculate concentrations in the ordinary way the activity of an ion in tenth-normal solution is always lower than that calculated from the behavior of more dilute solutions. The chloride ion from the tenth-normal potassium chloride has really then a smaller effect on the solubility of thallous chloride than we have ascribed to it when we assumed the complete validity of the ideal laws upon which the solubility-product rule is based. We shall adhere therefore to the first value, 0.6170 v., as the potential of the thallium electrode.

We also investigated saturated thallium amalgam in normal potassium chloride saturated with thallous chloride, and this furnished the most constant electrode of all those that we measured. With reasonable care it should give fully as reproducible a potential as the normal calomel electrode. Against the latter it has the following potential:[1]

$$\text{Tl, TlCl (solid), KCl } N,\text{ N. E.; } E = 0.8227 \text{ volt.}$$

---

[1] It is worth noting that the difference of 0.0521 v. between the electrodes in N and $1/10\,N$ KCl is almost identical with the difference of about 0.0526 v. between the normal and tenth-normal calomel electrodes.

This electrode, although it gives entirely reproducible potentials, shows a gradual increase of potential on long standing. This phenomenon had been observed to a greater degree with the other electrodes. Electrodes in saturated solutions of thallous chloride in water, 1/10 *N* KCl and *N* KCl respectively, increased in potential after four months' standing by 0.0038 volt, 0.0014 volt, and 0.0004 volt. We have not ascertained the cause of this increase. It is not due to any change in the amalgam, since in every case the original potential is obtained when the electrode vessel is refilled with a fresh solution.

Summary.

Contrary to some views previously published, there is nothing anomalous in the electromotive behavior of thallous ion, nor do we find any evidence of the existence of a sub-thallous ion.

Previous measurements of the thallium potential have been vitiated by the oxidation of the electrode and the consequent increase in thallous ion concentration. When such oxidation is avoided the Nernst formula is obeyed more closely than has been shown to be the case with any other electrode.

The assumption of the validity of the Nernst formula and the solubility-product rule (ion concentration being measured by conductivity) leads to measurable errors when the concentration is as high as tenth-normal, and the direction of these errors can be predicted.

The potential of pure thallium in saturated solutions of thallous chloride in water, in 1/10 *N* KCl and in *N* KCl were measured. The potential of pure thallium against (hypothetical) normal thallous ion is 0.6170 volt at 25° when the normal calomel electrode is taken as zero.

This work was completed in the summer of 1908.

Note.—Since this paper was written our attention has been called to an article by Brislee[1] who has investigated thallium potentials with precautions against the oxidation of the electrodes. He also finds no striking deviation from the Nernst equation although the variations which he observes are much larger than ours. This is doubtless because electrodes of solid thallium were used and because the work was not done in a thermostat. His value for the thallium electrode potential differs considerably from ours. We give below a table of values for the e. m. f. of Tl, Tl^+N, N. E. calculated from the results of the various observers whose work has been mentioned above. All the values are based on experiments with saturated thallous chloride.

	E. M. F.
Neumann	0.605
Abegg and Spencer	0.614
Brislee	0.602
Lewis and von Ende	0.6170
